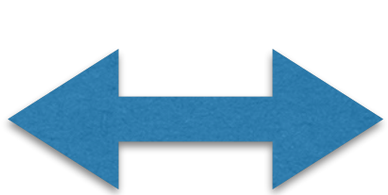
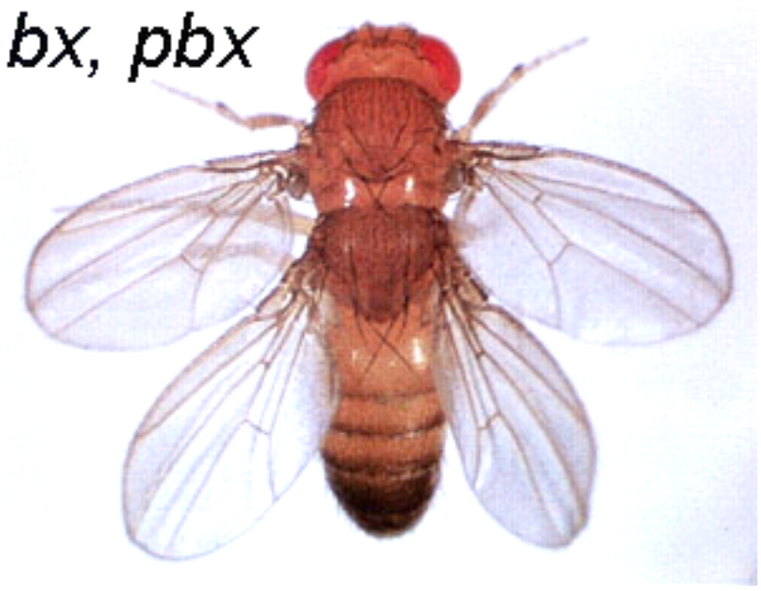
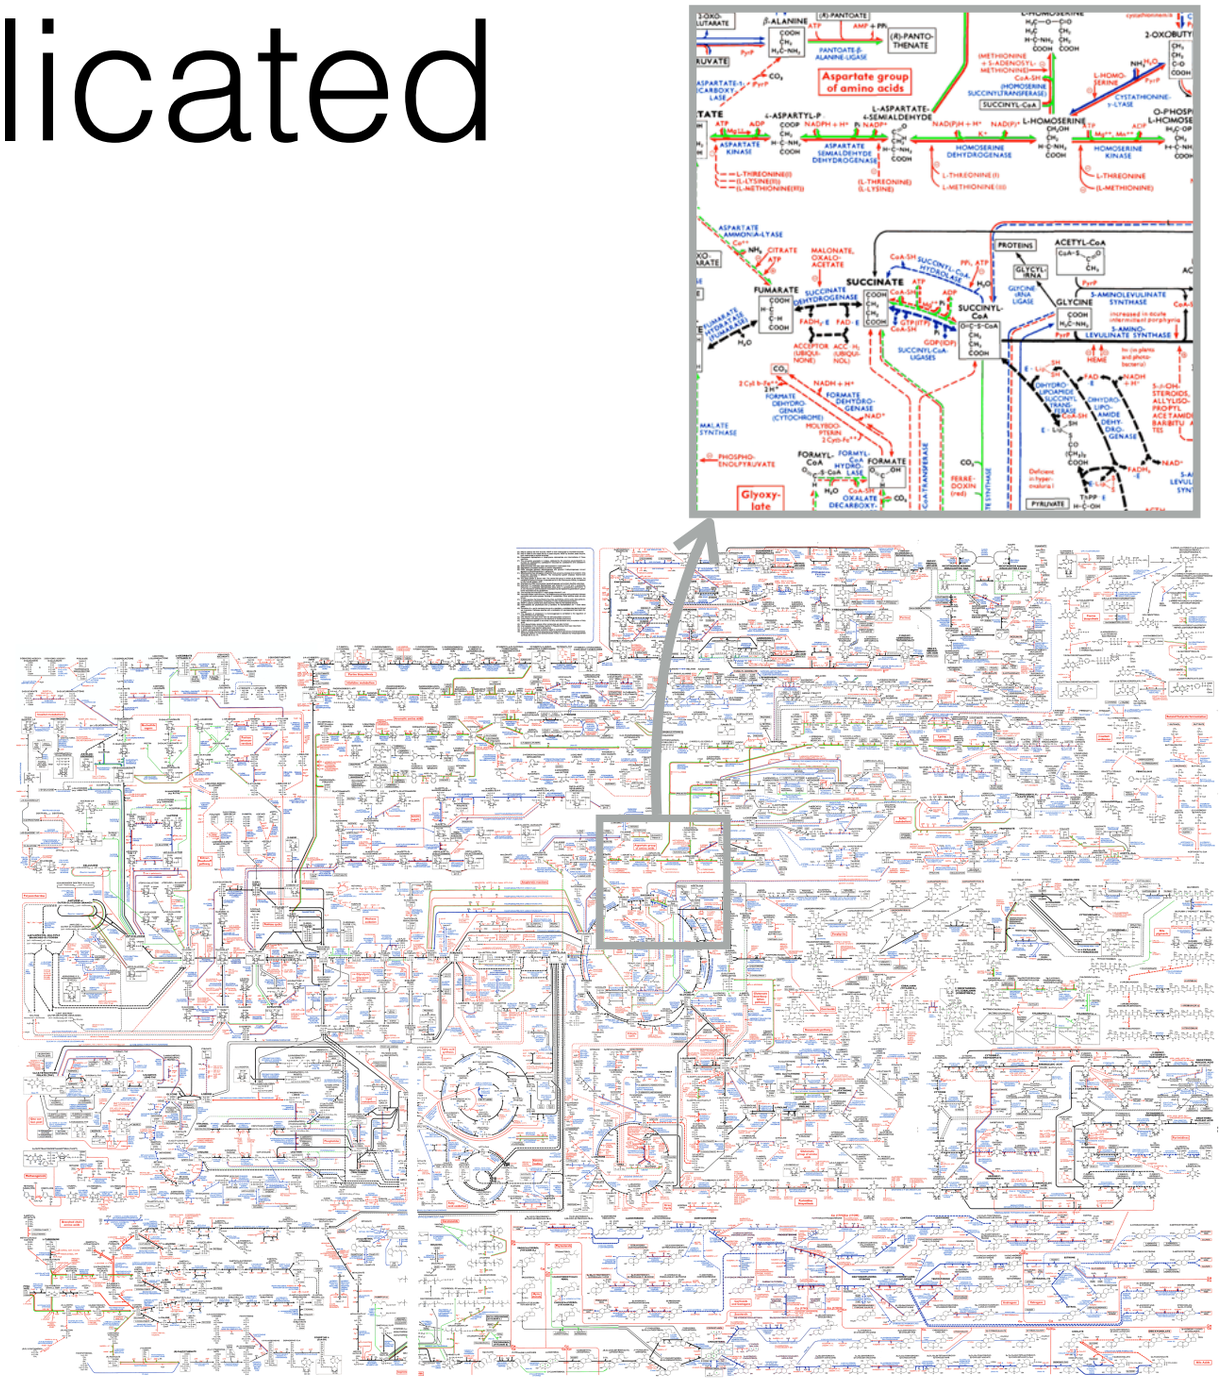
Genetic code behaves as a program



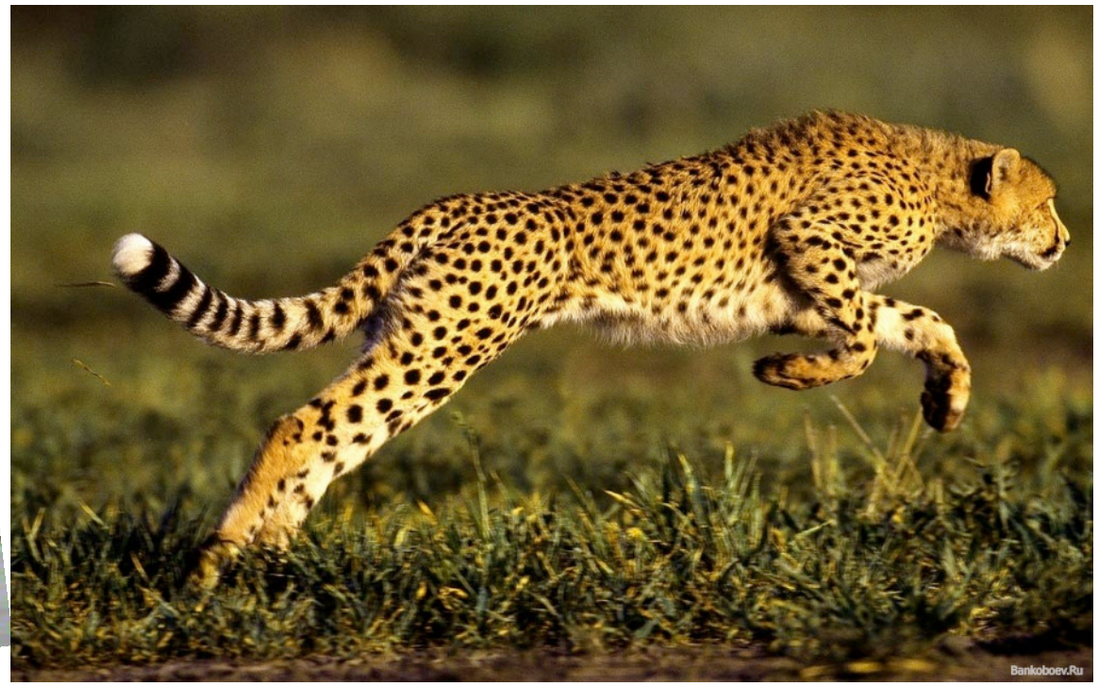


For instance, small changes in the code imply big differences

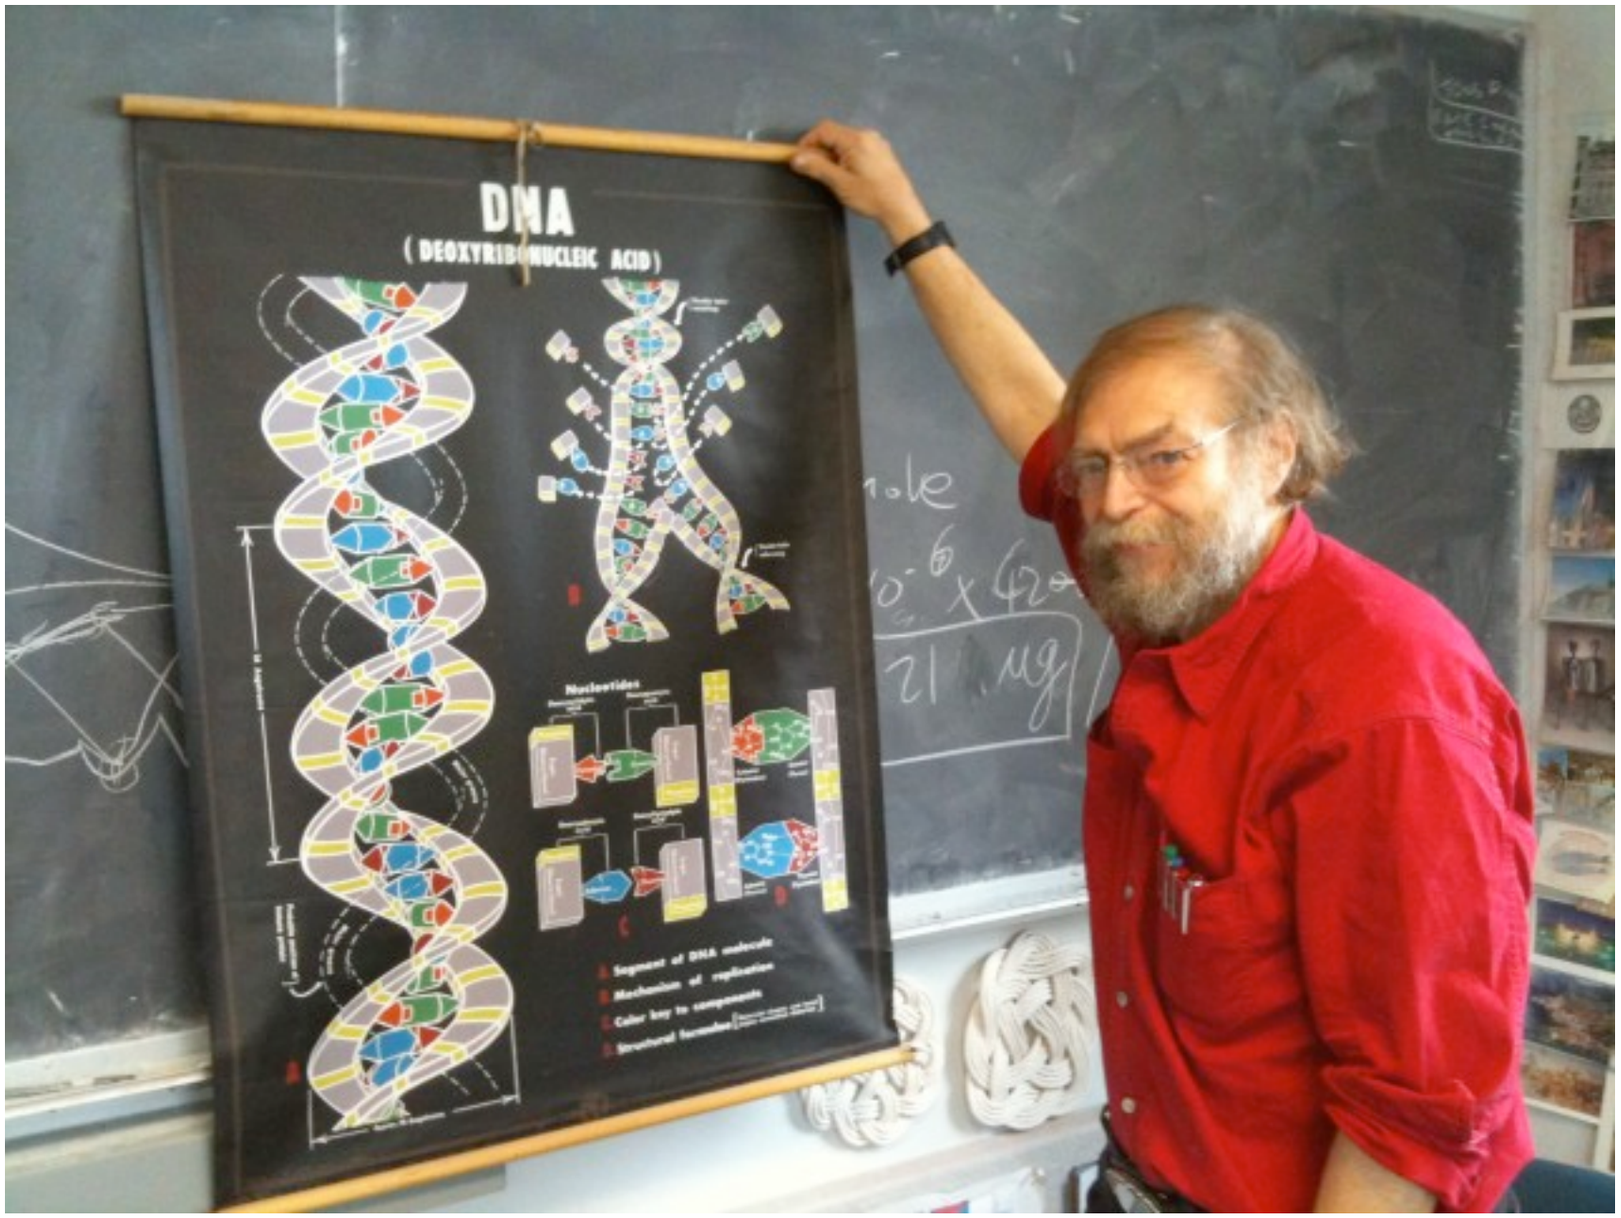
Nature is very complicated



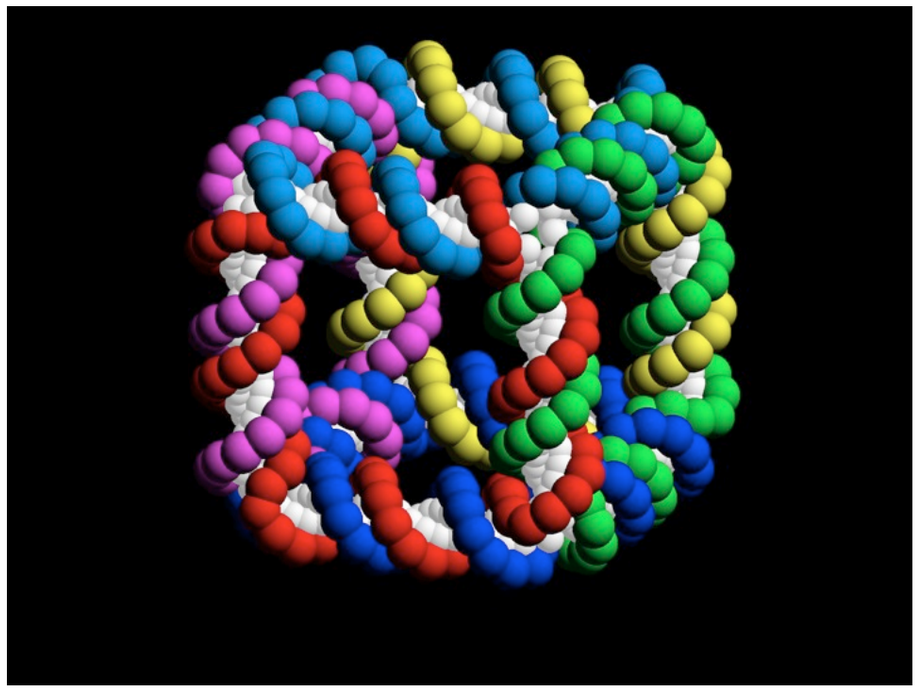
However we can try doing differently

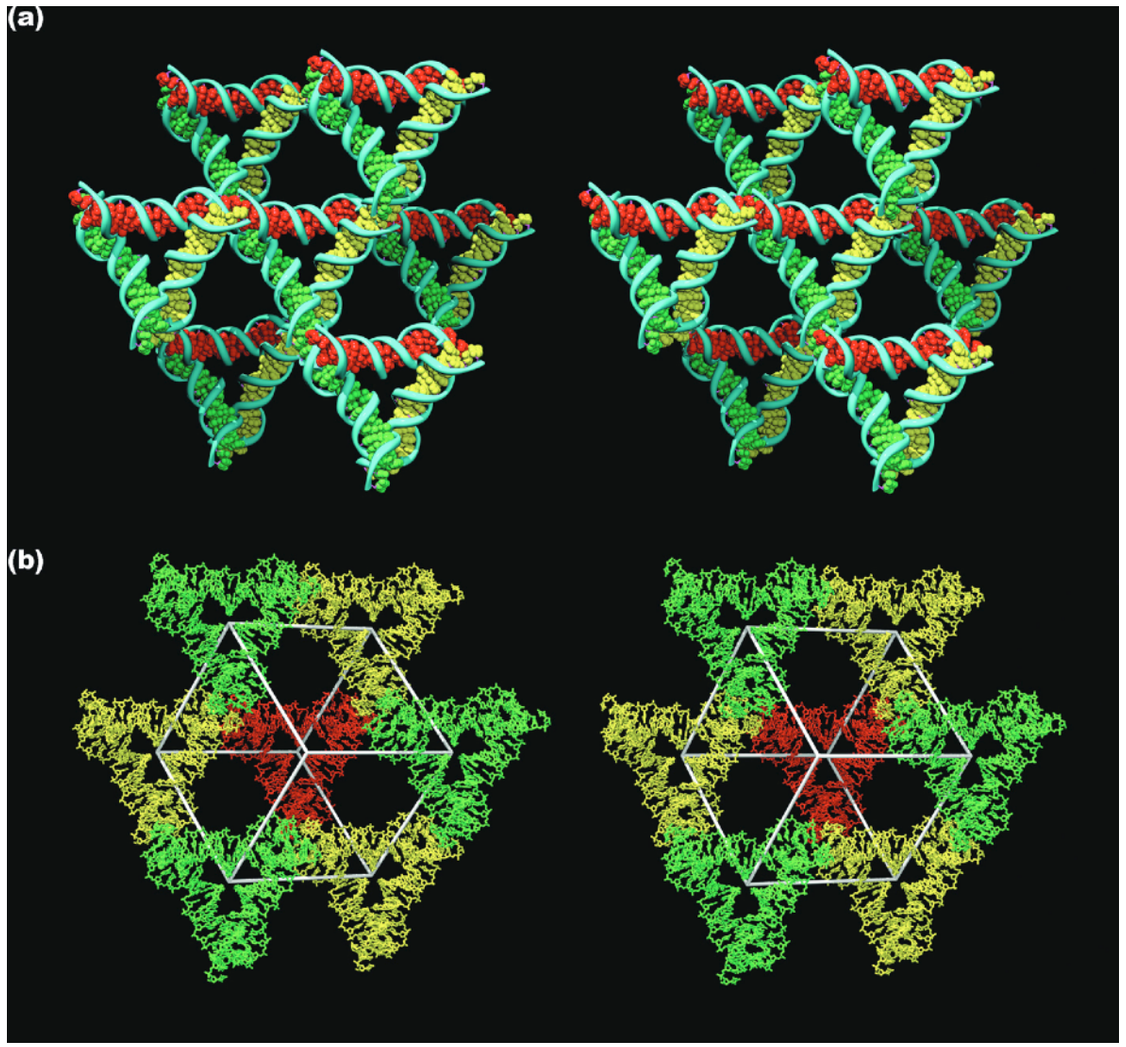


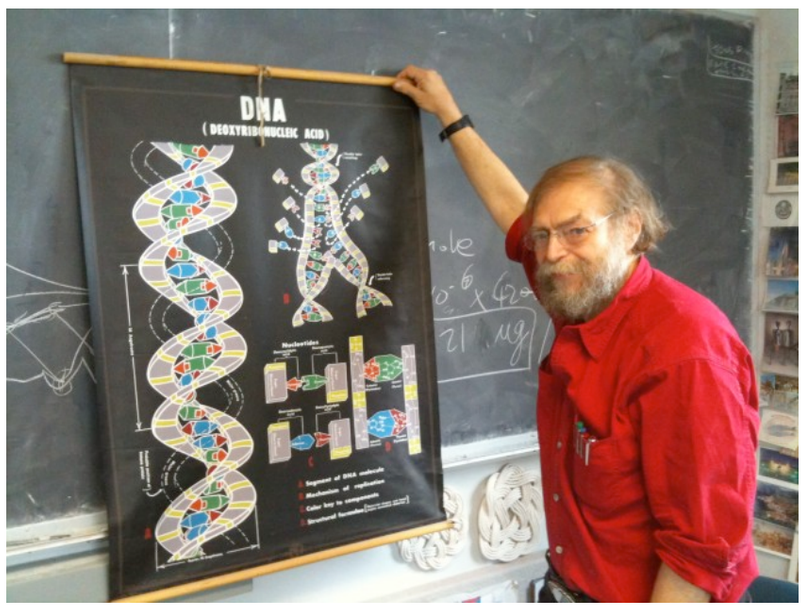
Using DNA to create shapes, Ned **Seeman** (1990-)



Using DNA to create shapes, Ned **Seeman** (1990-)







Create complementary strands inducing particular shapes

A tour of achievements

Why do we want to use nucleic acids to build structures, motors and circuits?

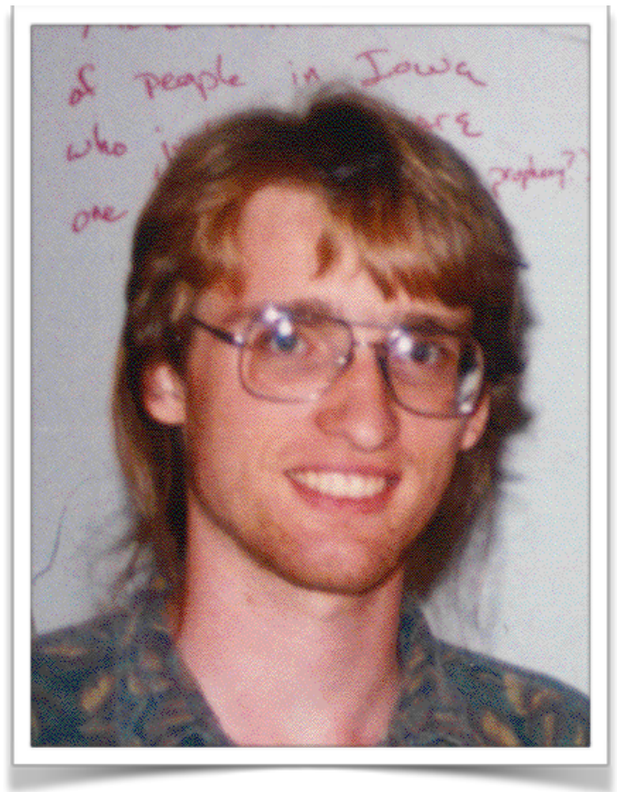
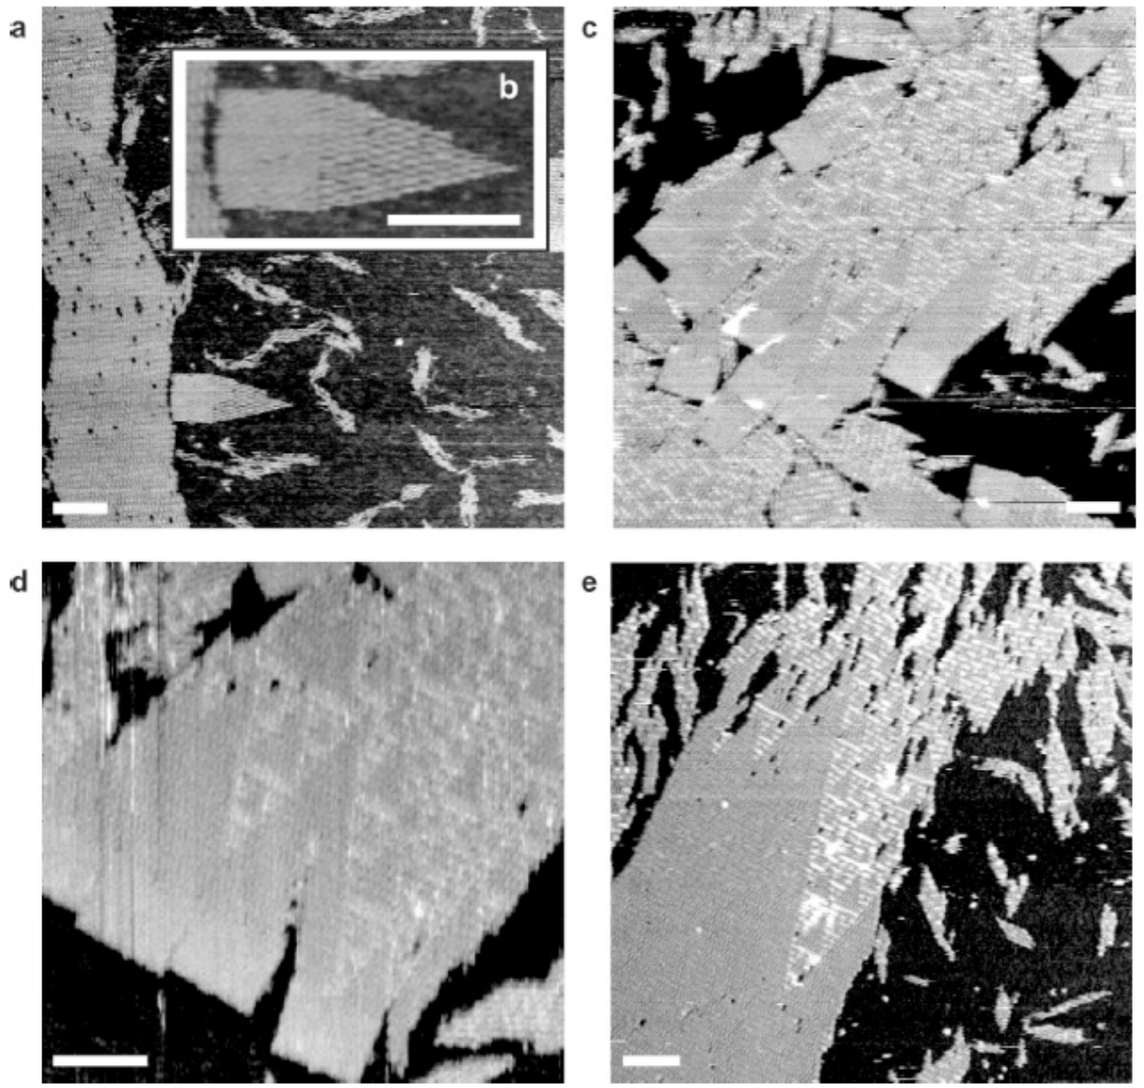
Part I: Tile assembly

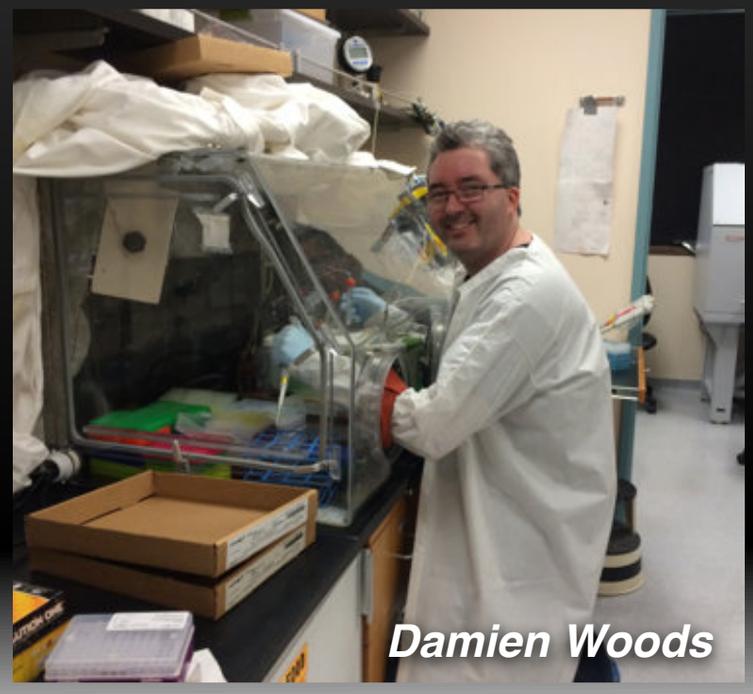
Erik **Winfree** (1998-): DNA algorithmic self-assembly

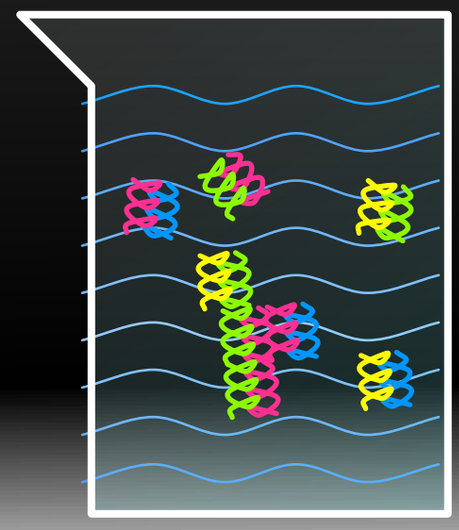




Principle of DNA algorithmic self-assembly

FedEx





1. Thermal cycler

Hot / less hot cycles for exponential duplication of the DNA strands by Polymerase Chain Reaction (PCR)

⇒ the tiles ..

2. One-pot reaction

Mixing the tiles at 90°C and letting the solution cool down to room temperature for few hours

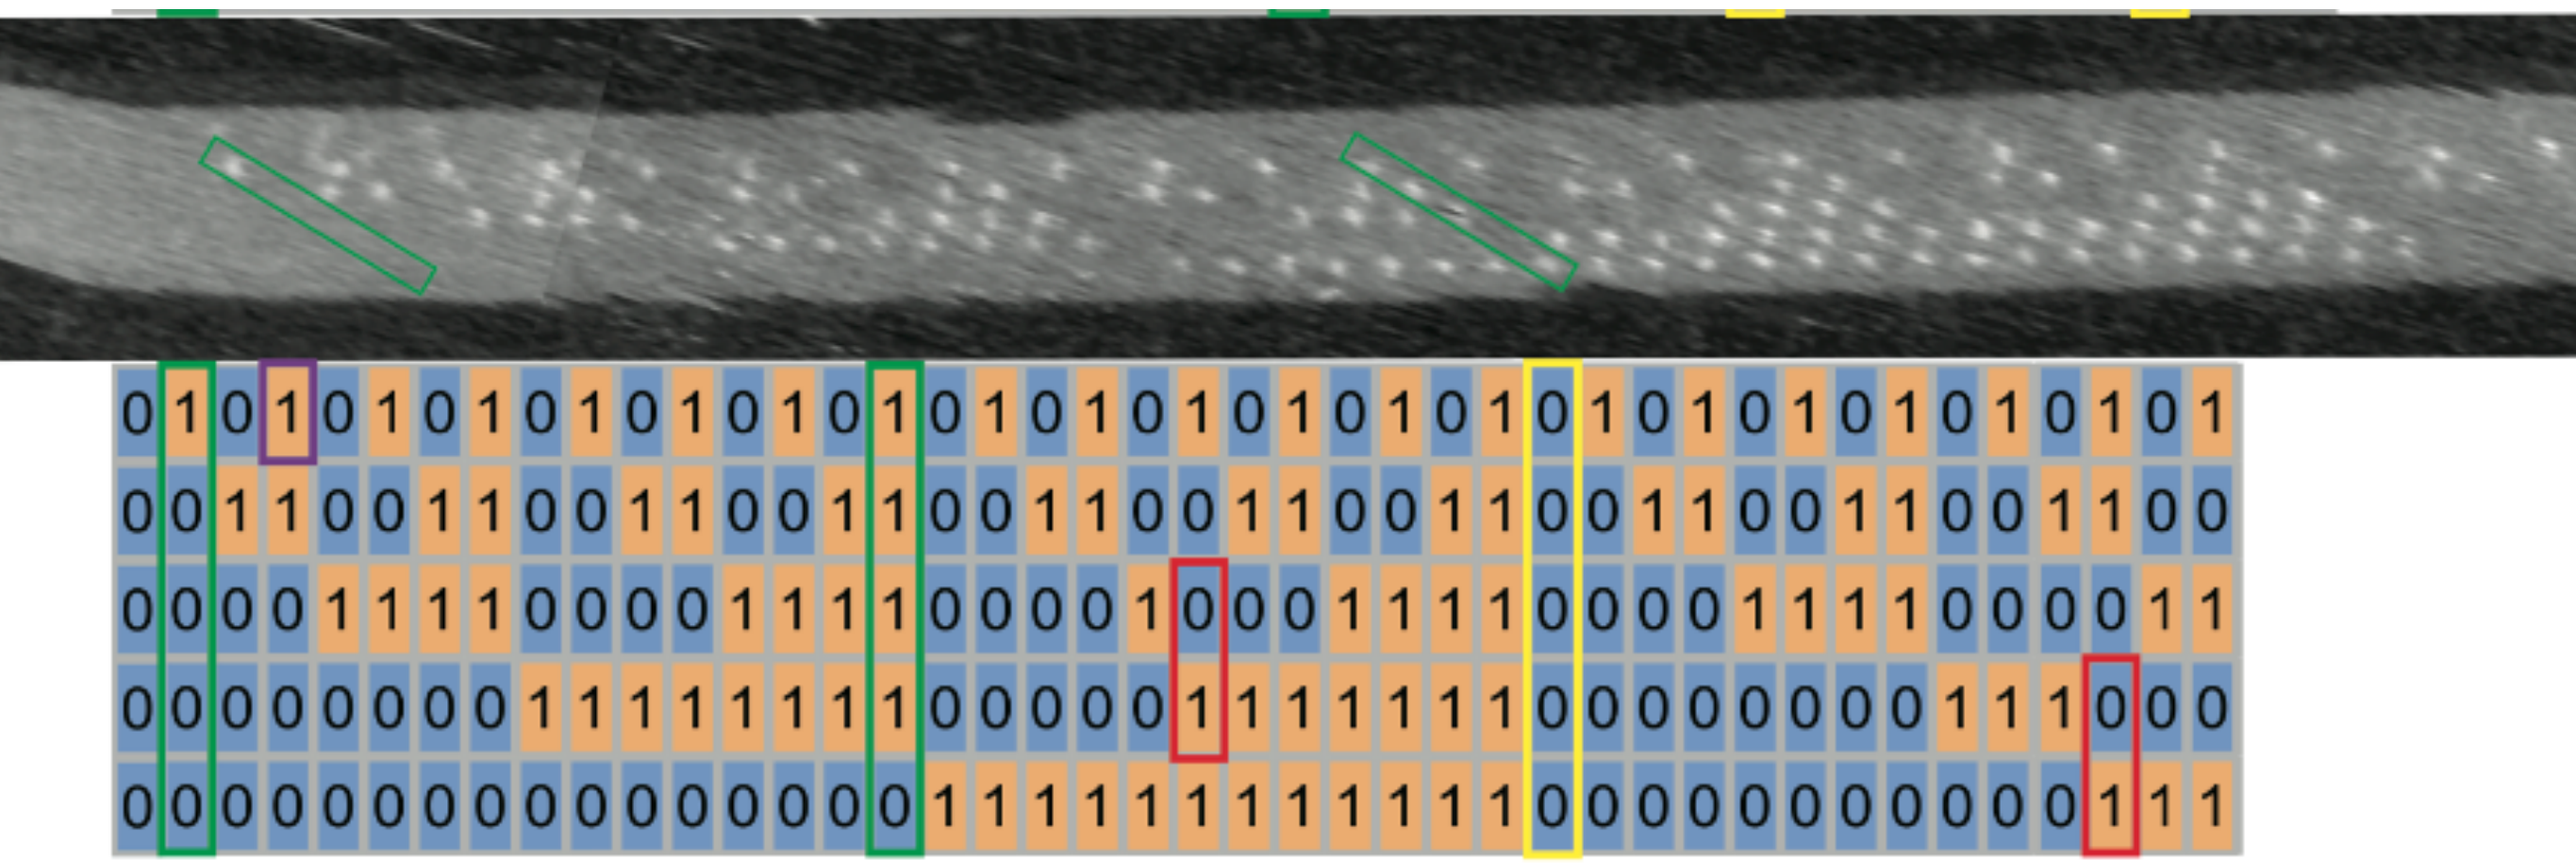
State of the art in experiments



Constantine Evans, PhD Thesis, Caltech 2014

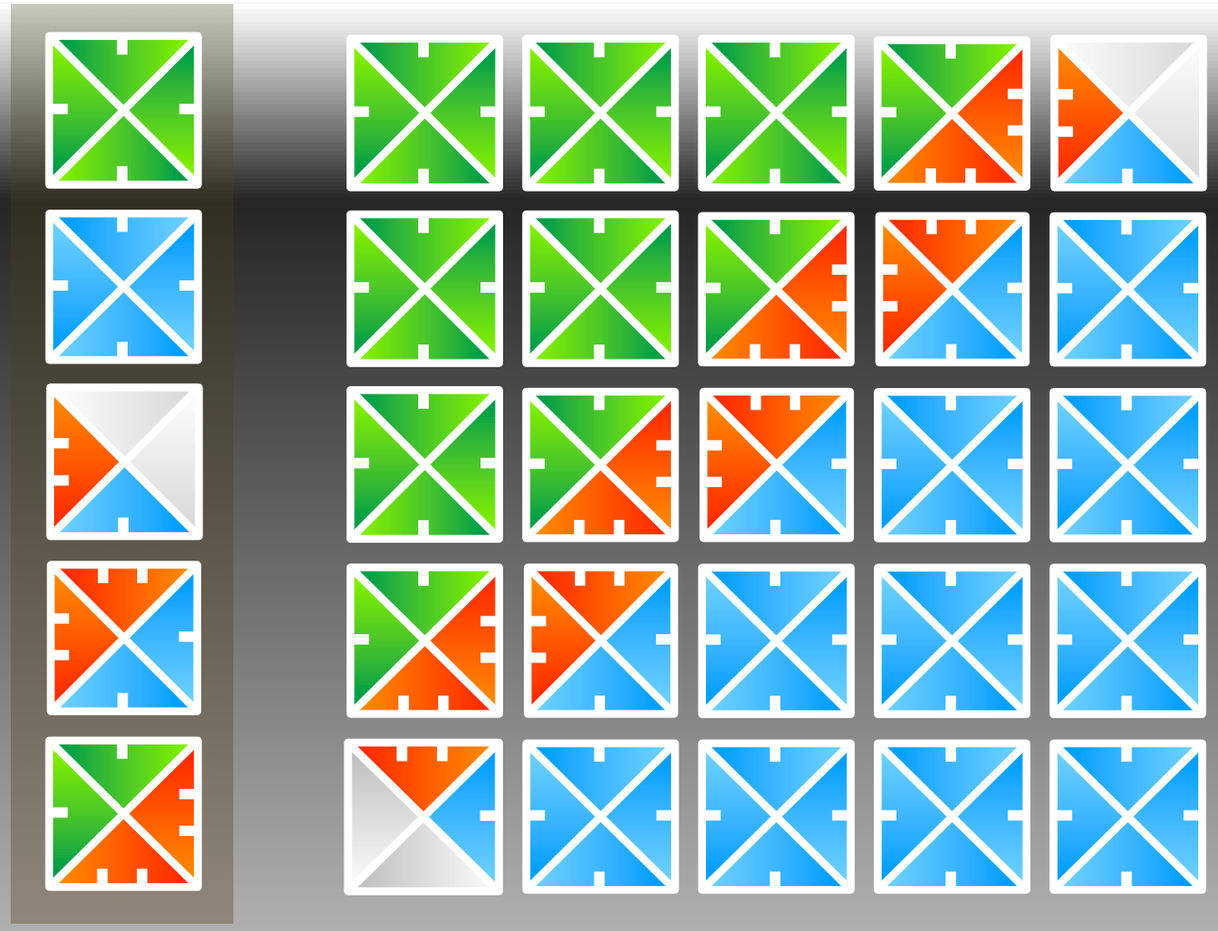
Algorithmic questions:

- Minimize the number of tiles?
- Minimize assembly time?
- Is there a universal set of tiles? (i.e. a programming language)

Minimize the number of tiles

- **Undecidable** problem in general
- For the square, **5 tiles are enough and required:**



Becker, Rapaport, Rémila, 2006

Minimizing Assembly time

- Undécidable problem in general
- Squares can be assembled in optimal time: 2n-2

Assembling vs Tiling & Cellular Automata

Facts

Irrevocability.
As opposed to CA, the "state/tile" of a cell cannot change

Everything that can bind, may bind so be careful with signals self-ignition.

Guaranteeing an order.
Being sure of the predecessors of each cell to guarantee the global behavior

Only one "main signal" per coordinate.
Otherwise it is not possible to guarantee the predecessors

Some consequences

Filling tiles carry information and are not interchangeable.
As opposed to quiescent states in CA or "blank tiles" in tilings

There exists flows of information within the shape.
Signals cannot go against the flows but still have to intersect predictably

Assembling vs Tiling & Cellular Automata

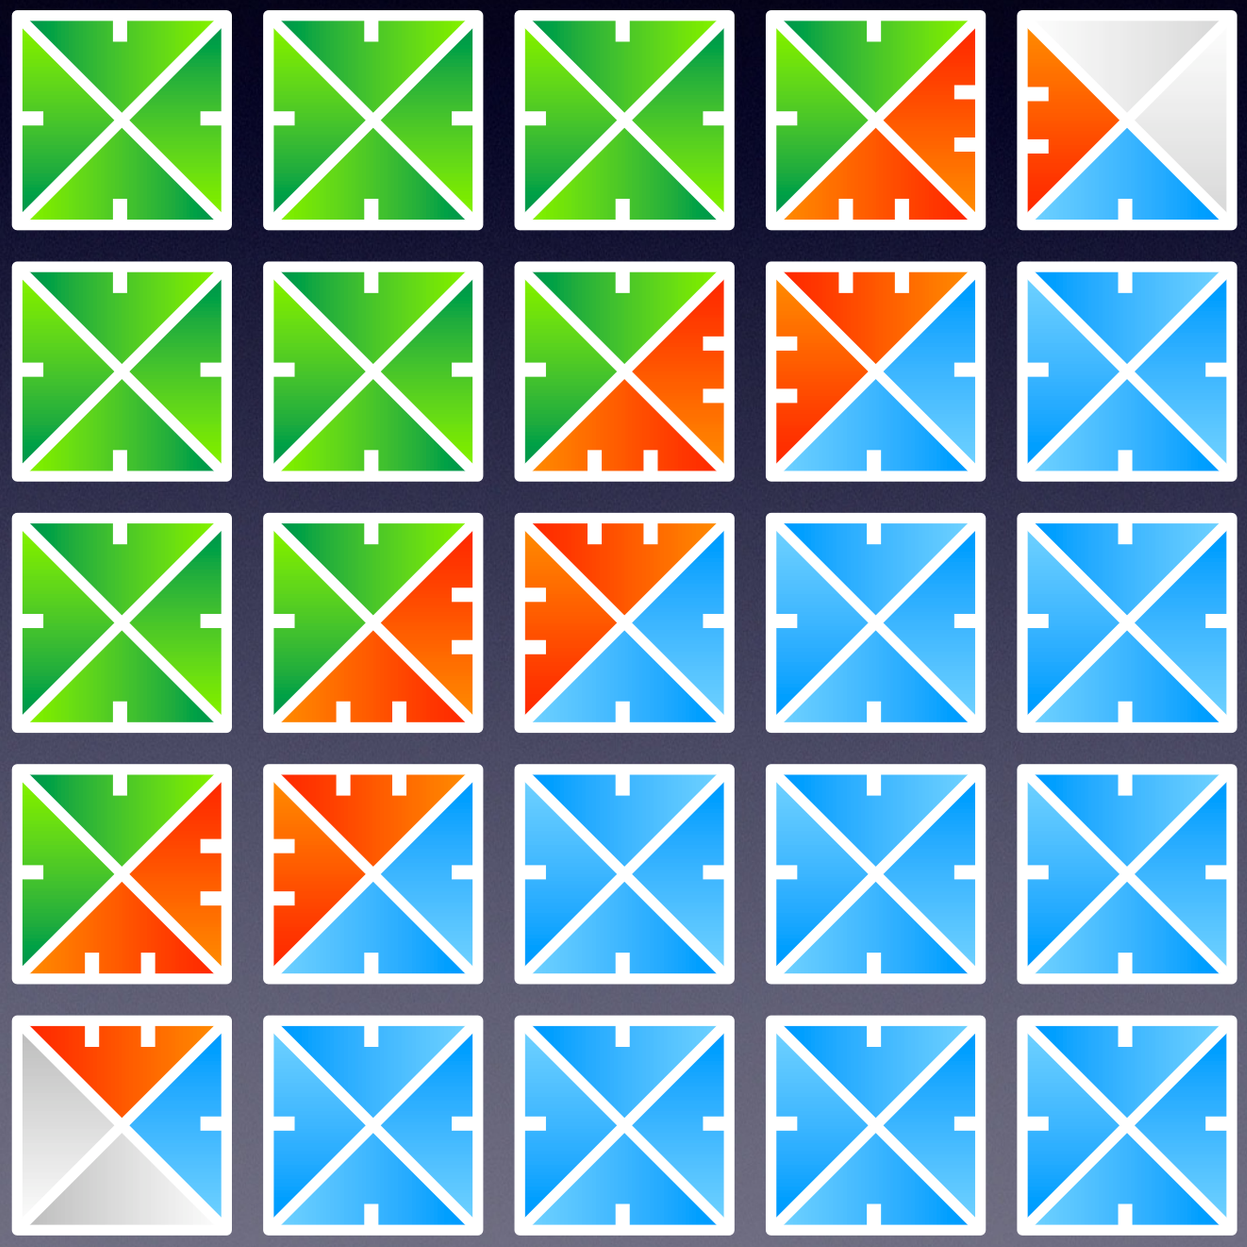
Ordered Tilesystem

A tilesystem is **ordered** *if for each production, the predecesors cells of each cell are* **independent** *of the construction path.*

Consequences

- *No one has more than* ***T° predecessors***.
- *The only* ***non-determinism*** *relies in the choice of the tile to attach, which determines which shape is assembled.*

Example of an ordered tile system



Example of an ordered tile system

the tiles - Temperature = 2

the seed

Example of an ordered tile system

Rank

Rank.
The **rank** of a site *(i,j)* in a given shape is the length of its longest chain of dependancies from the seed.

Time model

Poisson Markov Chain Model.
Each tile appears at each unoccupied site according to some Poisson process at a **rate** proportional to its **concentration**.

Only **matching** tile with **enough bonds** remains attached to the current agregate.

Time & order

Theorem. *[Adleman et al, 2001]*
The expected time to build a shape P is:

$$O(c \cdot rank(P))$$

where c only depends on the concentrations and $rank(P)$ is a highest rank in the shape P.

⇒ we focus on **minimizing the highest rank**

Real time

Lower bounding the construction time.
Given that tiles are placed one next to the others, $||P||_1$ is a lower bound on the highest rank of a site of a shape P.

Real time construction.
A shape P is built in **real time** if

the highest rank of a site $= ||P||_1$

For the $n \times n$ square S_n : $||S_n||_1 = 2n - 2$

Skeleton

understanding the flow of information

Skeleton. *The* ***skeleton*** *of a shape in an ordered tile system is the set of the sites with* ***at most one predecesor****.*

the *y*-skeleton in orange
opens the rows

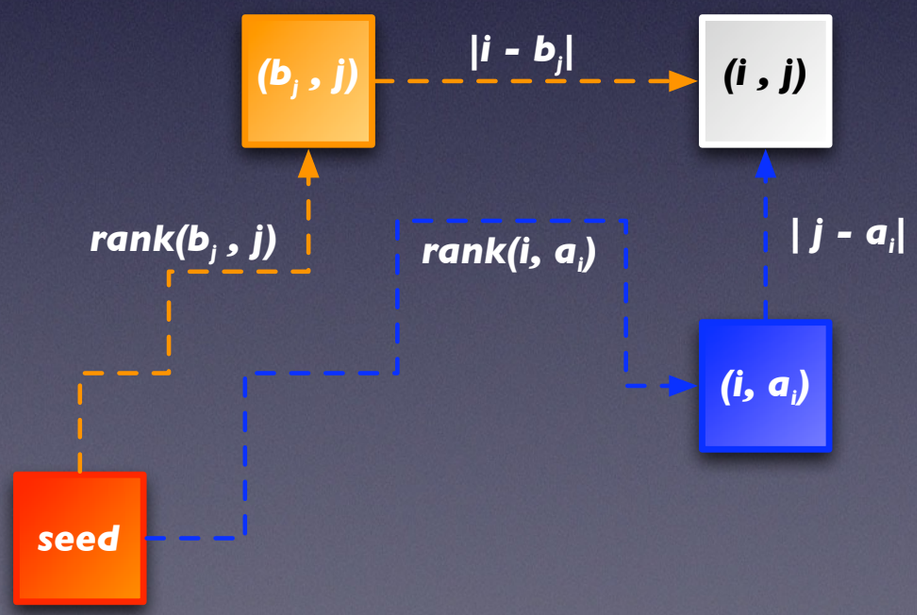
the *x*-skeleton in blue
opens the columns

Assembling a Square in Real Time

Lower bounding the rank

Let $(i, a_i)_{i \geq 0}$ and $(b_j, j)_{j \geq 0}$ be the *x*- and *y*-skeletons

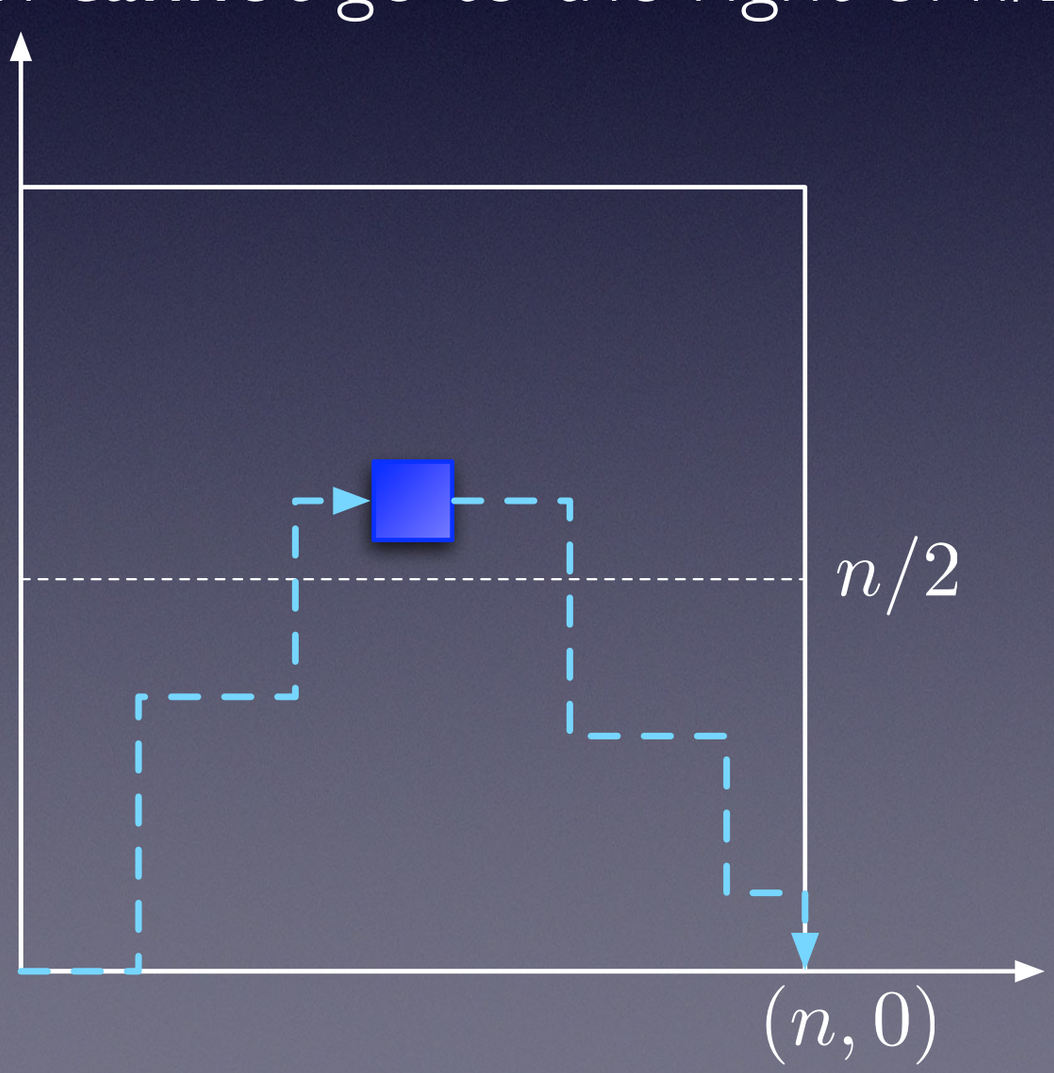
Since the *x*- and *y*-skeletons sites are the **first** tiled on each column and each row respectively, then for each site (i,j):



$$\mathrm{rank}(i,j) \geqslant \max\{\mathrm{rank}(i,a_i) + |j - a_i|, \mathrm{rank}(b_j,j) + |i - b_j|\}$$

Where should be the skeleton?

the x-skeleton **cannot** go above $n/2$
the y-skeleton **cannot** go to the right of $n/2$

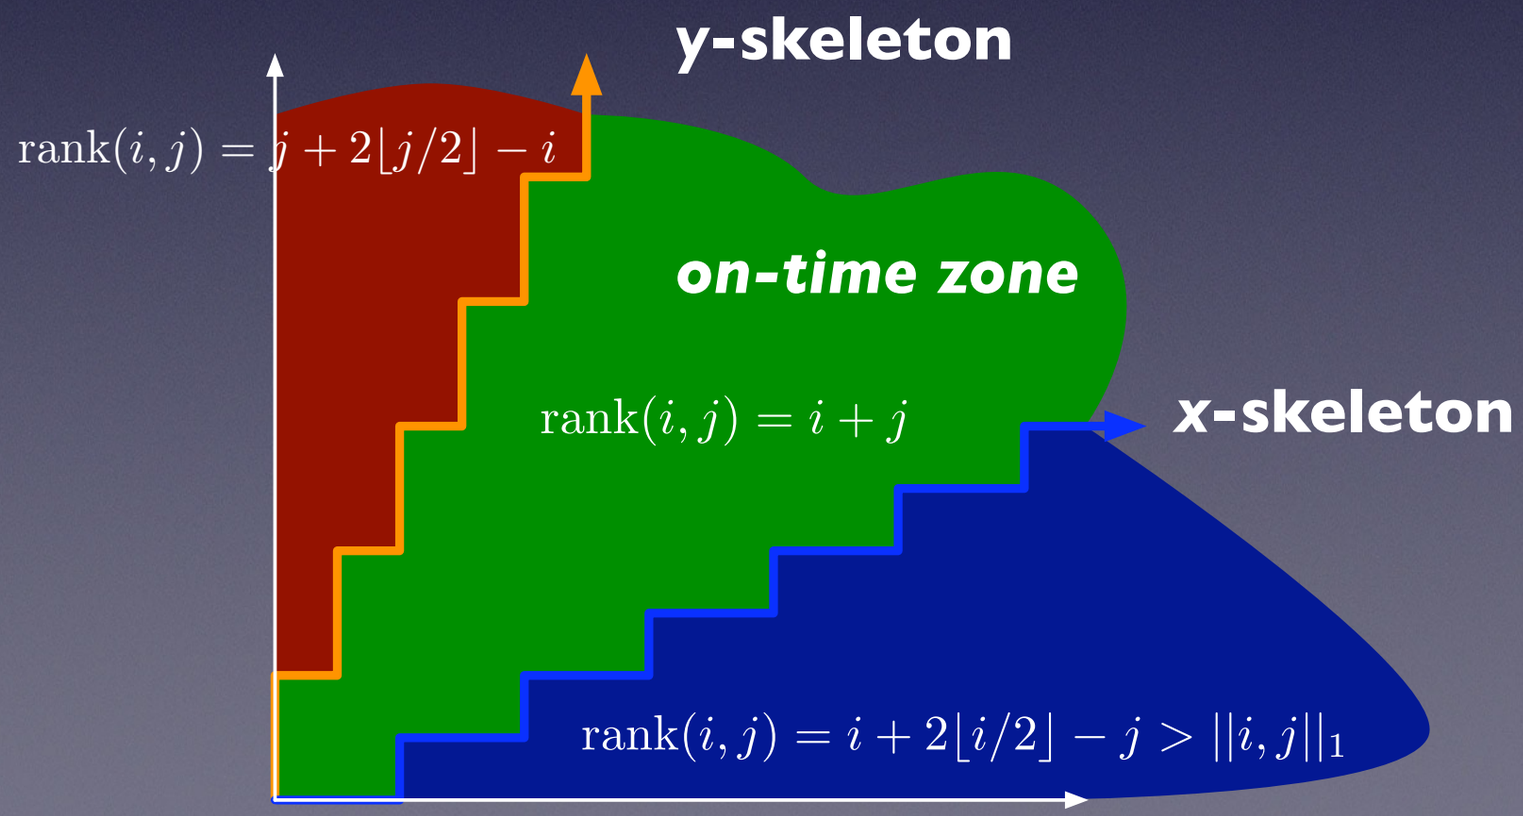


Rank function induced by the skeleton

The skeletons: $a_i = (i, \lfloor i/2 \rfloor)$ and $b_j = (\lfloor j/2 \rfloor, j)$

The rank induced:

$$rank(u) = \max\{||a_i||_1 + ||u - a_i||_1, |b_j||_1 + ||u - b_j||_1)$$



Order induced by the skeleton

Key to construct the tileset:

1) being able to **guess** the types of its **successors** from its own **predecesors**

2) **synchronizing** the two parts of the skeleton

The resulting tileset
