Abstract. The starting point of our work is a previous paper by Flarup, Koiran, and Lyaudet [8]. There the expressive power of certain families of polynomials is investigated. Among other things it is shown that polynomials arising as permanents of bounded tree-width matrices have the same expressiveness as polynomials given via arithmetic formulas. A natural question is how expressive such restricted permanent polynomials are with respect to other graph-theoretic concepts for representing polynomials over a field $\mathbb{K}$. One such is representing polynomials by formulas in conjunctive normal form. Here, a monomial occurs according to whether the exponent vector satisfies a given CNF formula or not. We can in a canonical way assign a graph to such a CNF formula and speak about the tree-width of the related CNF polynomial.
In this paper we show that the expressiveness of CNF polynomials of bounded tree-width again gives precisely arithmetic formulas. We then study how far the approach of evaluating subclasses of permanents efficiently using a reduction to CNF formulas of bounded tree-width leads. We show that no family of CNF polynomials of bounded tree-width can express general permanent polynomials. The statement is unconditional. In an earlier version of this paper [10] this result was obtained by reduction to an OBDD lower bound. Here we appeal instead to arguments from communication complexity. The present approach provides a new point of view on this problem; it also has the advantage of providing at little additional cost some new lower bounds, derived from communication complexity lower bounds in the so-called "best-case" model.
Finally, we observe that an analoguous impossibility result holds for CNF polynomials of bounded clique-width. This time the result is not unconditional : it relies on the assumption that $\#P \not\subseteq FP/poly$.
The paper contributes to the comparison between classical Boolean complexity and algebraic approaches like Valiant's one.

1 Introduction

An active field of research in complexity is devoted to the design of efficient algorithms for subclasses of problems which in full generality likely are hard to solve. It is common in this area to define such subclasses via bounding some significant problem parameters. Typical such parameters are the tree- and clique-width if a graph structure is involved in the problem's description.

In the center of the present paper stand problems related to families of polynomials. These families are given in a particular manner through certain Boolean formulas in conjunctive normal form, shortly CNF formulas. More precisely, we consider functions of the form

⋆ Support of the following institutions is gratefully acknowledged: ENS Lyon; the French embassy in Denmark, Service de Coopération et d'Action Culturelle, Ref.:39/2007-CSU 8.2.1; the Danish Agency for Science, Technology and Innovation FNU.

$$f(x) = \sum_{e \in \{0,1\}^n} \varphi(e) x^e, x \in \{0,1\}^n \text{ , for some } n \in \mathbb{N} \quad (*)$$

where φ is a CNF formula in n Boolean variables. We are interested in the question how expressive such a representation of polynomials is and under which additional conditions $f(x)$ can be evaluated efficiently. Fischer, Makowksy, and Ravve [7], extending earlier results from [3], have shown that the counting SAT problem, i.e. computing $\sum_{e \in \{0,1\}^n} \varphi(e)$ for a CNF formula φ can be solved in time $O(n \cdot 4^k)$ if a certain bipartite graph G_φ canonically attached to φ is of bounded tree-width k.

Our first main result precisely characterizes the expressive power of functions of form $(*)$ when G_φ is of bounded tree-width. It is shown that the class of these polynomials equals both the class of polynomials representable by arithmetic formulas of polynomial size and the class of functions obtained as permanents of matrices of bounded tree-width and polynomially bounded dimension. Here, equality of the latter two concepts was known before due to a result of Flarup, Koiran, and Lyaudet [8].

Recall that in Valiant's algebraic model of computation for families of polynomials the permanent is VNP complete and thus unlikely to be efficiently computable. Though an unconditional proof of this conjecture seems extremely difficult, we can at least show that trying to obtain an efficient algorithm for computing permanents through formulas of type $(*)$ with G_φ of bounded tree-width must fail. Such an algorithm would exist if the boolean function $\mathrm{PERM_n}$ recognizing $n \times n$ permutation matrices could be written as a (polynomial size) CNF formula of bounded treewidth. We show that such a CNF formula does not exist. This result is unconditional in that it does not rely on any open conjecture in complexity theory. In an earlier version of this paper [10] this impossibility result was obtained by reduction to an OBDD lower bound. Here we appeal instead to arguments from communication complexity (incidentally, this seems to be the first time that the $\mathrm{PERM_n}$ function is studied from the point of view of communication complexity). The present approach provides a new point of view on this problem; it also has the advantage of providing at little additional cost some new lower bounds for other functions, derived from communication complexity lower bounds in the so-called "best case" model.

Finally, we pose the corresponding question for CNF formulas of bounded clique-width. Using another result from [7] we show that expressing the permanent of an arbitrary matrix by formulas of type $(*)$, this time with G_φ of bounded clique-width would imply $\#P \subseteq FP/poly$ and thus is unlikely.

The paper is organized as follows. In Section 2 we recall basic definitions as well as the needed results from [7] and [8]. Section 3 first shows how permanents of matrices of bounded tree-width can be expressed via polynomials of form $\sum_{e \in \{0,1\}^n} \varphi(e) x^e$ with G_φ of bounded tree-width. Then, we extend a result from [7] to link such polynomials to arithmetic formulas. The results in [8] now imply equivalence of all three notions. In Section 4 the above mentioned negative results concerning expressiveness of (general) permanents by CNF formulas of bounded tree- or clique-width are proven.

Our results contribute to the comparison of Boolean and algebraic complexity. In particular, we consider it to be interesting to find more results like Theorem 7 below which states that certain properties **cannot** be expressed via (certain) graphs of bounded tree-width.

2 Basic definitions

In this section we collect the basic definitions and results that are needed below. We try to keep the section as short as possible since most of the notions are well known. Nevertheless, for the readers' convenience we collect all notions needed at one place.

2.1 Arithmetic circuits

Definition 1. *a) An arithmetic circuit is a finite, acyclic, directed graph. Vertices have in-degree 0 or 2, where those with indegree 0 are referred to as* inputs*. A single vertex must have outdegree 0, and is referred to as* output*. Each vertex of indegree 2 must be labeled by either $+$ or $\times$, thus representing computation. Vertices are commonly referred to as* gates*. By choosing as input nodes either some variables x or constants from a field $\mathbb{K}$ a circuit in a natural way represents a multivariate polynomial over $\mathbb{K}$.*

b) An arithmetic formula *is a circuit for which all gates exept the output have outdegree 1.*

c) The size *of a circuit is the total number of* gates *in the circuit.*

Note that for formulas the reuse of partial results is not allowed. For more on different subclasses of arithmetic circuits see [12].

2.2 Tree- and clique-width

Tree-Width for undirected graphs is defined as follows:

Definition 2. *Let $G = \langle V, E\rangle$ be a graph. A k-tree-decomposition of G is a tree $T = \langle V_T, E_T\rangle$ such that:*

(i) For each $t \in V_T$ a subset $X_t \subseteq V$ of size at most $k+1$.
(ii) For each edge $(u, v) \in E$ there is a $t \in V_T$ such that $\{u, v\} \subseteq X_t$.
(iii) For each vertex $v \in V$ the set $\{t \in V_T | v \in X_T\}$ forms a (connected) subtree of T.

The tree-width $twd(G)$ of G is then the smallest k such that there exists a k-tree-decomposition for G.

If we require the decomposition trees to be paths, then we obtain the path-width *of the given graph.*

The path-width of a graph G with n nodes can be bounded from above by $O(twd(G) \cdot \log n)$, see [2].

For the algorithmic treatment of CNF formulas below we recall the definition of H-sums of graphs, see [7].

Definition 3. *Let G_1, G_2 be two graphs that share (by isomorphy) a common induced subgraph H. The H-sum $G := G_1 \oplus_H G_2$ of G_1 and G_2 is the graph obtained by joining the vertices and edges of G_1 and G_2 while identifying the two copies of H in the new graph.*

Given a k-tree decomposition of a graph G with sets of vertices X_t, we can consider the subgraph H_t of G induced by X_t and reconstruct G using a sequence of H_t-sums.

Next we recall the clique-width notion.

Definition 4. *A graph G has* clique-width *at most k iff there exists a set of k labels $\mathcal{S}$ such that G can be constructed using a finite number of the following operations:*

i) $vert_a, a \in \mathcal{S}$ (create a single vertex with label a);

ii) $\phi_{a\to b}(H), a, b \in \mathcal{S}$ *(rename all vertices having label* a *to have label* b*);*
iii) $\eta_{a,b}(H), a, b \in \mathcal{S}, a \neq b$ *(add edges between all vertices having label* a *and all vertices having label* b*);*
iv) $H_1 \oplus H_2$ *(disjoint union of graphs).*

To each graph of clique-width k we can attach a (rooted) parse-tree whose leaves correspond to singleton graphs and whose vertices represent one of the operations above. The graph G then is represented at the root.

2.3 Permanent polynomials

Definition 5. *The permanent of an* (n, n)*-matrix* $M = (m_{i,j})$ *is defined as*

$$perm(M) := \sum_{\sigma \in S_n} \prod_{i=1}^{n} m_{i,\sigma(i)} \ ,$$

where S_n *is the symmetric group.*

We are interested in representing polynomials via permanents. If M above has as entries either variables or constants from some field $\mathbb{K}$, then $f = perm(M)$ is a polynomial with coefficients in $\mathbb{K}$ (in Valiant's terms f is a projection of the permanent polynomial). One main result in [8] characterizes arithmetic formulas of polynomial size by certain such polynomials. The tree-width of a matrix $M = [m_{ij}]$ is defined to be the tree-width of the graph including an edge (i, j) iff $m_{ij} \neq 0$.

Theorem 1. *([8]) Let* $(f_n)_{n\in\mathbb{N}}$ *be a family of polynomials with coefficients in a field* $\mathbb{K}$*. The following properties are equivalent:*

(i) $(f_n)_{n\in\mathbb{N}}$ *can be represented by a family of polynomial size arithmetic formulas.*
(ii) There exists a family $(M_n)_{n\in\mathbb{N}}$ *of polynomial size, bounded tree-width matrices such that the entries of* M_n *are constants from* $\mathbb{K}$ *or variables of* f_n*, and* $f_n = perm(M_n)$*.*

2.4 Clause graphs

One of our goals is to relate Theorem 1 to yet another concept, namely CNF formulas of bounded tree-width. The latter will be defined in this subsection. Our presentation follows closely [7].

Definition 6. *Let* φ *be a Boolean formula in conjunctive normal form with clauses* $C_1, \ldots, C_m$ *and Boolean variables* $x_1, \ldots, x_n$*.*

a) The signed clause graph $SI(\varphi)$ *is a bipartite graph with the* x_i *and the* C_j *as nodes. Edges connect a variable* x_i *and a clause* C_j *iff* x_i *occurs in* C_j*. An edge is signed* $+$ *or* $-$ *if* x_i *occurs positively or negated in* C_j*.*
b) The incidence graph $I(\varphi)$ *of* φ *is the same as* $SI(\varphi)$ *exept that we omit the signs* $+, -$*.*
c) The primal graph $P(\varphi)$ *of* φ *has only the* x_i*'s as its nodes. An edge connects* x_i *and* x_j *iff both occur commonly in one of the clauses.*
d) The tree- or clique-width of a CNF formula φ *is defined to be the tree- or clique-width of* $I(\varphi)$*, respectively.*
If below we want to speak about the tree-width of $P(\varphi)$ *we mention this explicitly.*

In [7] the authors prove:

Theorem 2. *a) Given φ and a tree-decomposition of $I(\varphi)$ of width k one can compute the number of satisfying assignments $\sum_{x\in\{0,1\}^n} \varphi(x)$ of φ in $4^k n$ arithmetic operations.*
b) Given a CNF formula φ and a parse-tree for the signed clause graph $SI(\varphi)$ of clique-width $\leq k$ the number $\sum_x \varphi(x)$ of satisfying assignments of φ can be computed in $O(n2^{ck})$ many arithmetic operations.

Below, we extend the algorithm proving Theorem 2 a) in order to relate CNF formulas to arithmetic formulas and to Theorem 1. Note that similar results to those of part a) of Theorem 2 have independently been obtained in [13].

3 Expressiveness of CNF polynomials of bounded tree-width

In this section we prove our first main result. We study how expressive polynomials p_n are which are given via CNF formulas φ_n of bounded tree-width. It turns out that permanents of bounded tree-width matrices are captured by such CNF polynomials, whereas the latter in turn are captured by arithmetic formulas. Given the equivalence stated in Theorem 1 all three concepts have the same expressive power.

3.1 From permanents to clause graphs

Theorem 3. *Let $M = [m_{ij}]$ be an $n \times n$ matrix such that the corresponding directed weighted graph $G_M = (V_M, E_M)$ is of tree-width k. Then there is a CNF formula φ of tree-width $O(k^2)$ and of size polynomially bounded in n such that*

$$perm(M) \;=\; \sum_{e,\theta} \varphi(e,\theta) \cdot m^e.$$

Here, $e = \{e_{i,j}\}$ denotes variables representing the edges of G_M, $m = \{m_{i,j}\}$ denotes the entries of M and $m^e := \prod_{i,j} m_{i,j}^{e_{i,j}}$, where $m_{i,j}^{e_{i,j}} = \begin{cases} m_{i,j} & \text{if } e_{i,j} = 1 \\ 1 & \text{if } e_{i,j} = 0 \end{cases}$.

For every e there exists θ such that $\varphi(e,\theta) = 1$ if and only if e is a cycle cover of G_M; in this case, the corresponding θ is unique.

Moreover, the number of additional variables θ is of order $O(n)$. Finally, a tree decomposition of $I(\varphi)$ of width $O(k^2)$ can be obtained from a decomposition of G_M in time $O(n)$.

Remark 1. In the above CNF polynomial $\sum_{e,\theta} \varphi(e,\theta) \cdot m^e$ there are no monomials corresponding to θ. Formally one could introduce another block y of variables and add to each monomial m^e another factor y^θ. Then $perm(M)$ is obtained as a projection (in Valiant's sense) of a CNF-polynomial $\sum_{e,\theta} \varphi(e,\theta) \cdot m^e \cdot y^\theta$ by plugging in for each y-variable the value 1.

Proof. Let $(T, \{X_t\}_t)$ be a tree decomposition of width k for G_M. Without loss of generality T is a binary tree. The CNF formula φ to be constructed contains two blocks of variable vertices, one being the edge-variables $e_{i,j}$ of G_M and another block θ of auxiliary variables to be explained below. The tree decomposition $(T, \{X'_t\}_t)$ that we shall construct for φ uses the same underlying tree T as the tree decomposition of G_M, but the boxes X'_t will be different from the boxes X_t in the initial decomposition.

A straightforward set of clauses to describe cycle covers in G_M is the following collection:

(i) for each vertex $i \in V_M$ clauses Out_i and In_i containing as its literals all outgoing edges from and all incoming edges into i, respectively;

(ii) for each $i \in V_M$ and each pair of outgoing edges $e_{i,j}, e_{i,l}$ a clause $\neg e_{i,j} \vee \neg e_{i,l}$; similarly for incoming edges to i.

A tree decomposition of the resulting formula then is obtained from T by taking the same tree and joining in a box X'_t for every $i \in X_t$ all vertices resulting from (i) and (ii). However, due to the conditions under (ii) this might not result in a decomposition of bounded width.

To resolve this problem for each box $t \in T$ and each $i \in V_M$ we add additional variables $check^t_{i+}, check^t_{i-}$. Fix t and the subtree T_t of T that has t as its root. For any assignment of the $e_{i,j}$ indicating which edges in G_M have been chosen for a potential cycle cover a condition $check^t_{i+} = 1$ indicates that an edge starting in i has already been chosen with respect to those vertices of G_M occurring in the subtree T_t.

Further clauses are introduced to guarantee that each i finally is covered exactly once for a satisfying assignment of $\varphi(e, \theta)$, where θ is the collection of all check variables. More precisely, we proceed bottom up. Let t be a leaf of T. For every $i \in X_t$ in addition to the variable vertices $check^t_{i+}, check^t_{i-}$ introduce clause variables representing the following clauses:

(1) $\bigvee_{j \in X_t} e_{i,j} \vee \neg check^t_{i+}$;
Interpretation: if none of the $e_{i,j}$'s where chosen yet, then $check^t_{i+} = 0$.
(2) $\neg e_{i,j} \vee \neg e_{i,l}$ for all $j, l \in X_t$;
Interpretation: at most one outgoing edge covers i.
(3) $\neg e_{i,j} \vee \neg check^t_{i+}$ for all $j \in X_t$;
Interpretation: if an $e_{i,j}$ was chosen (i.e. $e_{i,j} = 1$), then $check^t_{i+} = 1$.

Analogue clause variables are added for $check^t_{i-}$.

For the box X'_t in the decomposition of $I(\varphi)$ that corresponds to box X_t of T all variable vertices $e_{i,j}, check^t_{i+}, check^t_{i-}, i, j, \in X_t$ as well as the clause variables resulting from (1)-(3) above are included. These are $O(k^2)$ many elements in X'_t. Now T' is constructed bottom up. The check variables propagate bottom up the information whether a partial assignment for those $e_{i,j}$ that already occured in a subtree can still be extended to a cycle cover of G_M. At the same time, the width of the new boxes of T' constructed will not increase too much. Suppose in T there are boxes t, t_1, t_2 such that t_1 is the left and t_2 the right child of t. Let $i \in X_t \cap X_{t_1} \cap X_{t_2}$. The case where i only occurs in two or one of the boxes is treated similarly. Assuming X'_{t_1}, X'_{t_2} already been constructed the following clauses are included in X_t :

(1′) $\bigvee_{j \in X_t \setminus \{X_{t_1} \cup X_{t_2}\}} e_{i,j} \vee check^{t_1}_{i+} \vee check^{t_2}_{i+} \vee \neg check^t_{i+}$;
Interpretation: if all new $e_{i,j}$'s and the previous check variables are 0, then the new check variable $check^t_{i+}$ is 0 as well;
(2′) $\neg x \vee \neg y$ for all $x, y \in \{e_{i,j} : j \in X_t \setminus \{X_{t_1} \cup X_{t_2}\}\} \cup \{check^{t_1}_{i+}, check^{t_2}_{i+}\}; x \neq y$
Interpretation: at most one among the old check variables and the new edge variables gets the value 1;
(3′) $\neg x \vee \neg check^t_{i+}$ for all $x \in X_t \setminus \{X_{t_1} \cup X_{t_2}\} \cup \{check^{t_1}_{i+}, check^{t_2}_{i+}\}$;
Interpretation: if one among the values $e_{i,j}$ or $check^{t_1}_{i+}, check^{t_2}_{i+}$ is 1, then $check^t_{i+} = 1$.

Again, analogue clauses are added for the ingoing edges to i. Box X'_t contains all related edge vertices $e_{i,j}$ for the new $j \in X_t \setminus \{X_{t_1} \cup X_{t_2}\}$, the six check vertices and the $O(k^2)$ many clause vertices resulting from (1')-(3').

This way $(T, \{X'_t\}_t)$ is obtained. Finally, for each $i \in T$ two new clauses containing the single literals $check^r_{i+}$ and $check^r_{i-}$, respectively, are included in that box X_r which represents

the root r of the subtree of T generated by all boxes that contain i. This is to guarantee that i is covered in both directions.

Clearly, $(T, \{X'_t\}_t)$ is a binary tree with each X'_t containing at most $O(k^2)$ many vertices. Let θ denote the vector of all check variables. It is obvious from the construction that

$$\exists\theta\ \varphi(e,\theta) \Leftrightarrow e \text{ represents a cycle cover}$$

(via those $e_{i,j}$ that have value 1). Moreover, for each assignment of e^* giving a cycle cover there is precisely one assignment θ^* such that $\varphi(e^*,\theta^*) = 1$ because e^* uniquely determines which check variables have to be assigned the value 1. Therefore

$$perm(M) \ = \ \sum_{e,\theta} \varphi(e,\theta) \cdot m^e.$$

Finally, it remains to show that $(T', \{X'_t\}_t)$ actually is a tree decomposition of the graph $I(\varphi)$. Vertices resulting from check variables at most occur in two consecutive boxes of T' and thus trivially satisfy the connectivity condition. Clause vertices related to one of the construction rules (1), (3), $(1') - (3')$ for a fixed $t \in T$ only occur in the single box X'_t. Finally, an edge variable $e_{i,j}$ occurs in a box X'_t iff both i and j occur in X_t. Thus, the fact that $(T, \{X_t\}_t)$ is a tree decomposition implies that the connectivity condition also holds for these vertices and $(T', \{X'_t\}_t)$. □

3.2 From clause graphs to arithmetic formulas

In the next step we link CNF polynomials to arithmetic formulas. More precisely, the next theorem shows the latter concept to be strong enough to capture the former.

Theorem 4. *Let $\mathbb{K}$ be a field. Let $\{\varphi_n\}_n$ be a family of CNF formulas of bounded tree-width k and with n variables, $SI(\varphi_n)$ the related signed clause graphs and $(T_n, \{X_t\}_t)$ a tree decomposition of $I(\varphi_n)$. Then there is a family $\{f_n\}_n$ of polynomials with coefficients in $\mathbb{K}$ such that $\{f_n\}_n$ can be represented by a family of polynomially sized arithmetic formulas and*

$$f_n(x) = \sum_{z\in\{0,1\}^n} \varphi_n(z) \cdot x^z$$

for all $x \in \mathbb{K}^n$.

The proof is based on an extension of results in [7], namely Theorem 1.3. In the latter it is shown how to count efficiently satisfying assignments for a CNF formula φ, i.e. how to compute $\sum_{z\in\{0,1\}^n} \varphi_n(z)$, where $I(\varphi_n)$ is of bounded tree-width and a tree decomposition is given. Our extension is dealing with finding short arithmetic formulas for polynomials of the form $\sum_z \varphi(z) \cdot x^z$. The proof of Theorem 1.3. in [7] proceeds along a tree-decomposition of $I(\varphi_n)$ analyzing how the evaluation can be done for a clause graph G obtained as an H-sum of two other clause graphs G_1 and G_2, see Definition 3.

Our proof of Theorem 4 works as follows. We extend the ideas of [7] in order to show how one efficiently can evaluate $f_n(x)$ for all $x \in \mathbb{K}^n$ when f_n is defined as in the statement. Note that counting satisfying assignments corresponds to evaluating $f_n(1,\ldots,1)$. Taking the x_i's as variables the efficient algorithm obtained can then easily be converted into an arithmetic formula that has polynomial size.

Let us first adapt some notation from [7]. Let Σ be a set of clauses over a variable set V, let $W \subseteq V$ and $z : W \to \{0,1\}$ an assignment for the variables in W. Denote by $\varphi(\Sigma)$ the CNF

formula $\bigwedge_{C\in\Sigma} C$ and by $\Sigma^{(z)}$ the set of clauses obtained from Σ when replacing each $v \in W$ by the value $z(v)$.

The main part of the proof of Theorem 2 now is to analyze how the decomposition along H-sums used in [7] in order to calculate $\sum_z \varphi_G(z)$ can be extended to calculate as well $\sum_z \varphi_n(z)\cdot x^z$.

We need an additional definition:

Definition 7. *Let $\mathbb{K}$ be a field, G a clause graph with variable vertices $V, |V| = n, \varphi_G$ the corresponding CNF formula, $W \subseteq V$ and $z : W \to \{0,1\}$ a (partial) assignment for the variables in W.*

Then the polynomial $f_{(G,W,z)}$ is defined as

$$f_{(G,W,z)}(x) := \sum_{z':V\setminus W\to\{0,1\}} \left(\varphi_G(z',z)\cdot \prod_{i\in V\setminus W} x_i^{z'_i}\right) \ , \ \forall x \in \mathbb{K}^n.$$

Above the partial assignments z', z are plugged into φ_G in the obvious way.
In particular, if $W = \emptyset$ (and thus $z = \emptyset$) we define

$$f_{(G,\emptyset,\emptyset)}(x) := \sum_{z':V\to\{0,1\}} \varphi_G(z')\cdot x^{z'}.$$

The following technical proposition shows how $f_{(G,\emptyset,\emptyset)}(x)$ can be computed along an H-sum decomposition of G. As consequence Theorem 4 follows. We suppose the reader to be familiar with the proof of the related lemmata in [7].

Proposition 1. *Let G, G_1, G_2 be clause graphs with variable vertices V, V_1, and V_2, and clause vertices C, C_1, and C_2, respectively. Suppose that $G = G_1 \oplus_H G_2$, where H is an induced subgraph of G_1, G_2 with variable vertices W and clause vertices D. Let φ_1, φ_2 denote the CNF formulas related to G_1, G_2.*

a) For $D = \emptyset$ it is

$$f_{(G,\emptyset,\emptyset)}(x) = \sum_{z:W\to\{0,1\}} \left(f_{(G_1,W,z)}(x)\cdot f_{(G_2,W,z)}(x)\right)\cdot \prod_{i\in W} x_i^{z_i} \quad \forall x \in \mathbb{K}^n.$$

b) Suppose $W = \emptyset$ and $D = \{D_1, \ldots, D_m\}, m \in \mathbb{N}$. For an $X \subseteq \{1, \ldots, m\}$ and $i = 1, 2$ let $S_i(X)$ denote the set of clauses obtained from all $D_j, j \in X$ when only maintaining literals related to V_i. Finally, let $G_i(X)$ be the clause graph with variable vertices V_i and clause vertices $C_i \setminus S_i(X)$. Then

$$f_{(G,\emptyset,\emptyset)}(x) = \sum_{\ell=1}^{m} (-1)^\ell \sum_{\substack{X_1,X_2\subseteq\{1,\ldots,m\}\\ |X_1\cap X_2|=\ell}} f_{(G_1(X_1),\emptyset,\emptyset)}(x)\cdot f_{(G_2(X_2),\emptyset,\emptyset)}(x) \ .$$

c) Let both $W \neq \emptyset, D = \{D_1, \ldots, D_m\} \neq \emptyset$, then using the same notation as in b) one has for all $x \in \mathbb{K}^n$:

$$f_{(G,\emptyset,\emptyset)}(x) = \sum_{z:W\to\{0,1\}} \left(\sum_{\ell=1}^{m} (-1)^\ell \sum_{\substack{X_1,X_2\subseteq\{1,\ldots,m\}\\ |X_1\cap X_2|=\ell}} f_{(G_1(X_1),W,z)}(x)\cdot f_{(G_2(X_2),W,z)}(x)\right)\cdot \prod_{i\in W} x_i^{z_i}.$$

Proof. a) In [7] it is shown that

$$\sum_{z':V\to\{0,1\}} \varphi_G(z') = \sum_{z:W\to\{0,1\}} \left(\sum_{z^{(1)}:V_1\setminus W\to\{0,1\}} \varphi_1(z^{(1)},z) \right) \cdot \left(\sum_{z^{(2)}:V_2\setminus W\to\{0,1\}} \varphi_2(z^{(2)},z) \right) .$$

In order to extend this to the evaluation of polynomials one has to take care about not including the factor $\prod_{i\in W} x_i^{z_i}$ twice. This is the reason why defining $f_{(G,W,z)}$ as above. One gets

$$\begin{aligned} f_{(G,\emptyset,\emptyset)}(x) &= \sum_{z':V\to\{0,1\}} \left(\varphi_G(z') \cdot \prod_{i\in V} x_i^{z_i'} \right) \\ &= \sum_{z:W\to\{0,1\}} \left(\sum_{z^{(1)}:V_1\setminus W\to\{0,1\}} \varphi_1(z^{(1)},z) \cdot \prod_{i\in V_1\setminus W} x_i^{z_i^{(1)}} \right) \cdot \\ &\qquad \cdot \left(\sum_{z^{(2)}:V_2\setminus W\to\{0,1\}} \varphi_2(z^{(2)},z) \cdot \prod_{i\in V_2\setminus W} x_i^{z_i^{(2)}} \right) \cdot \prod_{i\in W} x_i^{z_i} \\ &= \sum_{z:W\to\{0,1\}} \left(f_{(G_1,W,z)}(x) \cdot f_{(G_2,W,z)}(x) \cdot \prod_{i\in W} x_i^{z_i} \right) \end{aligned}$$

as was claimed. Note that once a $z : W \to \{0,1\}$ has been fixed the expressions $f_{(G_i,W,z)}, i = 1,2$ have again the form $f_{(G_i',\emptyset,\emptyset)}$, where G_i' results from G_i by plugging the values for z into the clauses and then formally removing W. We thus can continue similarly for further decompositions of G.

b) This is basically Lemma 4.6 from [7]. The additional factors $\prod_{i\in V_1} x_i^{z_i^{(1)}}$ and $\prod_{i\in V_2} x_i^{z_i^{(2)}}$ do not change anything due to the fact that the variable vertex sets V_1 and V_2 are disjoint in this case.

c) As in [7] also the mixed case follows from a) and b) above. □

Proof. (of Theorem 4) Without loss of generality we suppose the tree decomposition $(T, \{X_t\}_t)$ of a given G to be of depth $O(\log n)$, see [1]. This will increase the tree-width by a constant factor only. [1] In order to find an arithmetic formula for $\sum_{z:V\to\{0,1\}} \varphi_n(z) \cdot x^z = f_{(G,\emptyset,\emptyset)}(x)$ we perform the dynamic programming algorithm provided by Proposition 1 bottom up along T. For each subgraph represented by a leave node the evaluation easily results in an arithmetic formula of length $2^{O(k)}$. When climbing up the tree at each node representing an H-sum operation the formulas resulting from the three cases of Proposition 1 contribute to the formula size by a factor of $2^{O(k)}$. Thus, since T has logarithmic depth the total formula size is of order at most $n^{O(k)}$. □

Theorems 1, 3 and 4 imply

Theorem 5. *Let $(f_n)_{n\in\mathbb{N}}$ be a family of polynomials with coefficients in a field $\mathbb{K}$. The following properties are equivalent:*

(i) $(f_n)_{n\in\mathbb{N}}$ can be represented by a family of polynomial size arithmetic formulas.
(ii) There exists a family $(M_n)_{n\in\mathbb{N}}$ of polynomial size, bounded tree-width matrices such that the entries of M_n are constants from $\mathbb{K}$ or variables of f_n, and $f_n = perm(M_n)$.

[1] Though it is de facto unnecessary to first balance T but makes the complexity arguments a bit easier.

(iii) There exists a family $(\varphi_n)_{n\in\mathbb{N}}$ of CNF formulas having polynomial size in n and of bounded tree-width such that $f_n(x)$ can be expressed as the projection: $f_n(x) = \sum_{\tilde{e}} \varphi_n(\tilde{e}) \cdot z^{\tilde{e}}$. Here, projection means that the z_i's can be taken either as constants from $\mathbb{K}$ or as variables among the x_j's. □

4 Lower bounds

Given Theorem 3 together with the efficient algorithm resulting from Theorem 4 the following question arises: How far does the approach of reducing permanent computations to computations of the form $\sum_{e,\theta} \varphi(e,\theta) \cdot m^e$ lead, when φ comes from a clause graph of bounded tree- or bounded clique-width?

Define the boolean function $\mathrm{PERM_n} : \{0,1\}^{\mathrm{n}\times\mathrm{n}} \to \{0,1\}$ as the function accepting the $n \times n$ permutation matrices, i. e. boolean matrices that have exactly one 1 in each row and one 1 in each column.

Formulated a bit differently we ask whether there exists a CNF formula $\varphi(e,\theta)$ of bounded tree- or clique-width, respectively, such that $\varphi(e,\theta) = 1$ iff $e \in \{0,1\}^{n\times n}$ is a permutation matrix and for each permutation matrix e there is exactly one θ s.t. $\varphi(e,\theta) = 1$.

In this section we prove that such a formula does not exist in case of tree-width. A second result shows that when replacing tree- by clique-width a formula with the above properties does not exist unless $\#P \subseteq FP/poly$.

4.1 Lower bound for tree-width

Towards our goal we employ results from communication complexity. We will relate it to the path-width of the primal graphs of formulas. Recall that the path-width of a graph with n nodes is bounded from above by $O(t \cdot \log n)$, where t denotes its tree-width [2].

In order to be able to argue on primal graphs we need the following result that justifies the replacement of a formula's incidence graph by its primal graph.

Proposition 2. *Let $\varphi = C_1 \wedge \ldots \wedge C_m$ be a CNF formula with n variables $x_1, \ldots, x_n$ such that its incidence clause graph $I(\varphi)$ has tree-width k. Then there is a CNF formula $\tilde{\varphi}(x,y)$ such that the following conditions are satisfied:*

- *each clause of $\tilde{\varphi}$ has at most $O(k)$ many literals;*
- *the primal graph $P(\tilde{\varphi})$ has tree-width $O(k)$. A tree-decomposition can be constructed in linear time from one of $I(\varphi)$;*
- *the number of variables and clauses in $\tilde{\varphi}$ is linear in n;*
- *for all $x^* \in \{0,1\}^n$ it is $\varphi(x^*)$ iff there exists a y^* such that $\tilde{\varphi}(x^*, y^*)$. Such a y^* moreover is unique.*

Proof. Let $(T, \{X_t\}_t)$ be a (binary) tree-decomposition of $I(\varphi)$. The construction below combines the use of check variables in the proof of Theorem 3 with the usual way of reducing a general CNF formula instance to one with bounded number of literals in each clause. Let C be a clause of φ and T_C the subtree of T induced by C. We replace C bottom up in T_C by introducing $O(n)$ many new variables and clauses. More precisely, start with a leaf box X_t of T_C. Suppose it contains $k+1$ variables that occur in literals of C, without loss of generality say $x_1 \vee \ldots \vee x_{k+1}$. Introduce a new variable y_t together with $O(k)$ many clauses expressing the equivalence $y_t \Leftrightarrow x_1 \vee \ldots \vee x_{k+1}$. Each of the new clauses has at most $k+2$ many literals. Next, consider an inner node t of T_C having two sons t_1, t_2. Suppose $x'_1, \ldots, x'_{k+1}$ to be those variables in X_t that occur as literals in C, again without loss of generality in the form $x'_1 \vee \ldots \vee x'_{k+1}$.

If y_{t_1}, y_{t_2} denote the new variables related to C that have been introduced for X_{t_1}, X_{t_2}, for X_t define a new variable y_t together with clauses expressing $y_t \Leftrightarrow y_{t_1} \vee y_{t_2} \vee x'_1 \vee \ldots \vee x'_{k+1}$. Again, there are at most $O(k)$ new clauses containing $O(k)$ literals each. Finally, if t is the root of T_C we define y_t as before and add a clause saying $y_t = 1$.

Do the same for all clauses of φ. This results in a CNF formula $\tilde{\varphi}$ which depends on $O(m \cdot n)$ additional variables y and contains $O(m \cdot n \cdot k)$ many clauses. The construction guarantees that $\varphi(x)$ iff there exists a y such that $\tilde{\varphi}(x, y)$ and in that case y is unique.

A tree-decomposition of the primal graph $P(\tilde{\varphi})$ is obtained as follows. For each occurrence of a clause C in X_t of T replace the clause vertex by the newly introduced y variables related to the clause and the box X_t. In addition, for boxes X_t, X_{t_1}, X_{t_2} such that t_1, t_2 are sons of t include the variables y_{t_1}, y_{t_2} also in the upper box X_t. The x_i variables that previously occurred are maintained. Since for a single box X_t at most three y_j are included for each clause, and since there are at most $k + 1$ clause vertices in an original box, the tree-width of $P(\tilde{\varphi})$ is $\leq 4(k + 1)$. The decomposition satisfies the requirements of a tree-decomposition since we did not change occurrences of the x_i's and the only y_t-variables that occur in several boxes occur in two consecutive ones. □

Our proofs below rely on definitions from communication complexity which we briefly recall. For more on this see [11].

Definition 8. *Let $f : \{0,1\}^n \mapsto \{0,1\}$ be a Boolean function.*

a) Consider a partition of the n variables of f into two disjoint sets $x = \{x_1, \ldots, x_{n_1}\}, y = \{y_1, \ldots, y_{n_2}\}, n_1 + n_2 = n$. The communication complexity of f with respect to (x, y) is the lowest amount of bits that two processors, the first working on the variables x and the second on the variables y, need to exchange in order to compute f in common.

b) The one-way communication complexity of f with respect to (x, y) is the lowest amount of exchanged bits needed to compute f if only one processor is allowed to send bits to the other.

c) If above we only allow variable partitions of same cardinality, i.e., n is even and $|x| = |y|$, and minimize over all of them we obtain the best-case and best-case one-way communication complexity, respectively.

d) The non-deterministic communication complexity of f with respect to (x, y) is the lowest amount of bits that two processors, the first working on the variables x, the second on the variables y, and each having access to a source of non deterministic bits, need to exchange in order to compute in common the function f in the following sense :

- *If $f(x) = 1$, at least one of the possible non-deterministic computations must be accepting*
- *If $f(x) = 0$, all the non-deterministic computations must be non-accepting.*

A useful approach in communication complexity consists in considering for a given function $f(u, v)$ the matrix associated to it :

Definition 9. *Let $f : U \times V \to \{0,1\}$ be a boolean function.*

a) We call the matrix of f the matrix $(f(u, v))$, where the different assignments of u denote the rows and those to v denote the columns.

b) A rectangle of the matrix $(f(u, v))$ is a set of entries composed of the intersection of a certain set of rows and a certain set of columns. That is, a set of entries R is a rectangle if and only if the following is true : $\exists \tilde{U} \subseteq U, \tilde{V} \subseteq V$ such that $R = \tilde{U} \times \tilde{V}$.

c) A rectangle of the matrix $(f(u, v))$ is called monochromatic if f has the same value on each entry of the rectangle.

The following two results are classical in communication complexity [11, 14] :

Theorem 6. *Let $f(x, y)$ be a function over two boolean vectors x and y.*

(i) The one-way communication complexity of f equals the logarithm of the number of different rows in the matrix $(f(u, v))$.
(ii) The non-deterministic communication complexity of f equals the logarithm of the minimal number of monochromatic rectangles of the matrix $(f(u, v))$ needed to cover all values 1 in the matrix.

For the lower bound proof the non deterministic communication complexity of certain partitions is the crucial notion. The following lemma relates it to the path-width of primal graphs.

Lemma 1. *Let $\phi(e, \theta)$ be a CNF formula depending on $n+s$ variables and $f : \{0,1\}^n \mapsto \{0,1\}$ a Boolean function such that :*

- *if $\phi(e, \theta) = 1$, then $f(e) = 1$*
- *if $f(e) = 1$, then there exists a θ such that $\phi(e, \theta) = 1$.*

Consider an arbitrary path-decomposition $(X_1, \ldots, X_p)$ of $P(\phi)$ of width k. Choose a node X_i of the decomposition and a partition x, y of the variables e such that all variables of type e that have already occurred among those in $X_1, \ldots, X_{i-1}$ are distributed to x and all the ones that never occur in $X_1, \ldots, X_i$ to y. Then the non-deterministic communication complexity of f with respect to (x, y) is at most $k + 2$.

Proof. We split ϕ as follows into two CNF formulas ϕ_1 and ϕ_2 such that $\phi = \phi_1 \wedge \phi_2$ and ϕ_1 and ϕ_2 have at most $k + 1$ variables in common. Formula ϕ_1 is made of all clauses in ϕ that only contain variables that appear in $X_1, \ldots, X_{i-1}$. The remaining clauses are collected in ϕ_2. Due to the path-width conditions only variables in X_i can be common variables of ϕ_1 and ϕ_2.

One remarks, that all variables in x that appear in ϕ_2 must belong to X_i, and that no variables in y appear in ϕ_1.

Now given an assignment of the variables (x, y), let the first processor complete its assignment x by guessing non-deterministically the values of the remaining variables needed to compute ϕ_1 - that is, variables of θ since no variables in y appear in ϕ_1. Similarly, the second processor completes its assignment of y by guessing the values of the remaining variables appearing in ϕ_2 - variables of θ, and variables of x appearing in X_i as remarked previously.

Let the first processor send to the second processor the result of its computation of ϕ_1 along with the values of the variables in its assignment that ϕ_2 also uses. Those are variables in x appearing in ϕ_2, and variables from θ that are common to ϕ_1 and ϕ_2. Thus they all appear in X_i. As a result, the first processor sends at most $|X_i| + 1 \leq k + 2$ bits.

With those values, the second processor can check if the values of its guesses are consistent with the values the first processor had, and if both the computations of ϕ_1 and ϕ_2 are accepting.

Thus, if $e = (x, y)$ does not satisfy f, no guesses of the variables θ could complete e in an assignment that satisfy both ϕ_1 and ϕ_2 and the protocol will never be accepting; and if $f(e) = 1$, then if the two processors guess the proper values to compute ϕ_1 and ϕ_2 on the existing assignment (e, θ) that satisfies ϕ, both ϕ_1 and ϕ_2 will be satisfied, and the protocol will be accepting. □

Remark 2. At the end of this section we obtain a similar lemma in order to obtain some results of independent interest relating best-case deterministic communication complexity and path-width.

An outline of the lower bound proof is as follows: Given a CNF formula for the function $\mathrm{PERM_n}$ and a variable partition as above we next define certain permutations called balanced. The number of balanced permutations can be upper bounded in terms of the non-deterministic

communication complexity, by Lemma 2. Then in Lemma 3 we show that a CNF formula for the permanent function gives rise to a variable partition with relatively many balanced permutations. Combining this with Lemma 1 above and the well known relation between path- and tree-width gives the following lower bound result:

Theorem 7 (lower bound for the permanent). *Let $(\phi_n)_{n\in\mathbb{N}}$ be a family of CNF formulas $\phi_n(e,\theta)$ in n^2 variables $e=(e_{ij})$ and s_n auxiliary variables θ such that :*

- *if $\phi_n(e,\theta)=1$, then the matrix $e\in\{0,1\}^{n\times n}$ is a permutation matrix*
- *if $e\in\{0,1\}^{n\times n}$ is a permutation matrix, then there exists θ such that $\phi_n(e,\theta)=1$.*

Then the path-width $p(n)$ of the primal graphs $P(\phi_n)$ verifies $p(n)=\Omega(n)$, and the tree-width $t(n)$ verifies $t(n)=\Omega(n/\log(n+s_n))$.

As a result, the general permanent function cannot be expressed by a family of CNF-formulas with a polynomial number of auxiliary variables and an incidence graph of bounded tree-width.

Remark 3. The above lower bounds are independent of the size of the CNF formula.

Remark 4. It seems possible to improve the $t(n)=\Omega(n/\log(n+s_n))$ lower bound by working directly with tree decompositions instead of path decompositions. The proofs would get more cumbersome but do not seem to require new ideas. We therefore stick to path decompositions in the remainder of this section.

We proceed as outlined above with

Definition 10. *For $n\in\mathbb{N}$ let $\phi_n(e,\theta)$ be a CNF formula in n^2 variables $(e_{ij})_{1\le i,j\le n}$ and s variables $\theta_1,\dots,\theta_s$, s arbitrary. Consider a variable partition (x,y) of e. A permutation $\pi:\{1,\dots,n\}\mapsto\{1,\dots,n\}$ is called* balanced with respect to the partition (x,y) *if among the n variables $e_{i,\pi(i)}, 1\le i\le n$ precisely $\lceil\frac{n}{2}\rceil$ belong to x and $\lfloor\frac{n}{2}\rfloor$ belong to y.*

Thus, if (e_{ij}) represents a permutation matrix and π is balanced, then (almost) half of those e_{ij} with value 1 belong to x and the other half to y.

Lemma 2. *Let $\phi_n(e,\theta)$ be a CNF formula which evaluates to 1 only if e is a permutation matrix as in the statement of Theorem 7. Suppose ϕ_n has n^2 variables $e=(e_{ij})$ and s_n variables θ, and let x,y be a variable partition of e. If there are m balanced permutations with respect to (x,y), then the non-deterministic communication complexity c of the function $f_n:=\mathrm{PERM_n}$ with respect to (x,y) satisfies*

$$m \;\le\; 2^c\cdot\left(\lceil\frac{n}{2}\rceil!\right)^2 \;.$$

Proof. Consider the matrix $(f_n(x,y))$ as defined in Theorem 6, where rows and columns are marked by the possible assignments for x and y, respectively. If π is a permutation which is balanced with respect to (x,y), we denote by $(x(\pi),y(\pi))$ the corresponding assignments for the (e_{ij}) and we denote by $R(\pi)$ the row of index $x(\pi)$ in the communication matrix $(f_n(x,y))$.

We wish to compute an upper bound K such that any monochromatic rectangle covers at most K balanced permutations. The point then is that the communication matrix will have at least m/K distinct rectangles since there are m balanced permutations. We can then conclude that $m\le 2^c\cdot K$ by Theorem 6.

Towards this aim let A be a rectangle covering the value 1 corresponding to π in the matrix. A is the intersection of a certain set of rows and a certain set of columns. Since π is covered by A, $R(\pi)$ belongs to that set of rows. Let C be one of the columns.

The intersection of $R(\pi)$ and C belongs also to A, and thus contains a 1. Thus, the assignment y_c indexing C completes $x(\pi)$ in a satisfying assignment of f_n. Since π is balanced, there

are $\lceil n/2 \rceil$ variables set to 1 in $x(\pi)$. If $x(\pi), y_c$ are to form a permutation matrix, y_c must have exactly $\lfloor n/2 \rfloor$ variables set to 1, distributed in the intersection of the $\lfloor n/2 \rfloor$ rows and columns without any 1 in the assignment $x(\pi)$.

Thus, there are at most $\lfloor n/2 \rfloor!$ possible values for y_c, and thus at most $\lfloor n/2 \rfloor!$ possible columns in A. Symmetrically, there are at most $\lceil n/2 \rceil!$ possible rows in A. Finally one can take $K = \lceil n/2 \rceil! \cdot \lfloor n/2 \rfloor!$, and the conclusion of the lemma follows from the inequality $m \leq 2^c \cdot K$. □

The final ingredient for the lower bound proof is

Lemma 3. *Let ϕ_n be as in Lemma 2. There exists a partition of e into two variable sets x, y such that this partition is as in the statement of Lemma 1 and such that there are at least $n! \cdot n^{-2}$ many balanced permutations with respect to (x, y).*

Proof. Let $(X_1, X_2, \ldots, X_p)$ be the nodes of a path-decomposition of $P(\phi_n)$ (in that order). We define an ordering on the e_{ij}'s as follows: for an e_{ij} let $\underline{X}(e_{ij})$ be the first node in the path-decomposition containing e_{ij}. We put $e_{ij} < e_{kl}$ if $\underline{X}(e_{ij}) < \underline{X}(e_{kj})$. If both values are equal for e_{ij} and e_{kl} we order them arbitrarily but in a consistent way to achieve transitivity.

Consider a permutation π. There are precisely n among the variables corresponding to an $e_{i\pi(i)}$. We pick according to the above order the $\lceil \frac{n}{2} \rceil$-st among those and denote it by e_π. Thus, among the $e_{i\pi(i)}$ exactly $\lfloor \frac{n}{2} \rfloor$ are greater than e_π and $\lceil \frac{n}{2} \rceil$ are less than or equal to e_π with respect to the defined order. By the pigeonhole principle there is at least one variable e_ℓ among the n^2 many e_{ij}'s such that for at least $\frac{n!}{n^2}$ many permutations of $\{1, \ldots, n\}$ we get that same e_ℓ by the above procedure, i.e., $e_\pi = e_\ell$ for all those π. We choose a partition (x, y) of the e_{ij} as follows. The part x consists of all the variables e_{ij} that are less than or equal to e_ℓ, and the part y of the variables that are greater than v_ℓ. The partition (x, y) is as stated in Lemma 1, where the node $\underline{X}(e_\ell)$ plays the role of the X_i in the Lemma. The above arguments imply that at least $\frac{n!}{n^2}$ many permutations are balanced with respect to this variable partition. □

Proof (of Theorem 7). Let ϕ_n be as in the theorem's statement. According to Lemma 3 there is a variable partition with at least $\frac{n!}{n^2}$ many balanced permutations. According to Lemmas 2 and 1 the path-width k of $P(\phi_n)$ satisfies

$$\frac{n!}{n^2} \leq 2^{k+2} \times (\lceil n/2 \rceil!)^2 \ .$$

Using Stirling's formula we deduce that $k = \Omega(n)$. Now the tree-width t of ϕ_n satisfies $t \in \Omega(k/\log(n + s_n))$ which results in $t \in \Omega(n/\log(n + s_n))$. Finally, the statement about the tree-width of ϕ_n's incidence graph follows from Proposition 2. □

Remark 5. The lower bound obtained above seems not derivable from the known lower bounds on computing the permanent with monotone arithmetic circuits, see, e.g., [9]. The tree-width based algorithms for polynomial evaluation like the one in [7] are not monotone since they rely on the principle of inclusion and exclusion.

We close this subsection by strengthening slightly Lemma 1 in order to apply it also to the best-case communication complexity (Definition 8) and obtain some lower bound results of independent interest.

Lemma 4. *Let ϕ be a CNF formula depending on $2n$ many variables. Assume that the primal graph $P(\phi)$ has path-width $k-1$. Then ϕ can be split into two CNF formulas $\phi_1 \wedge \phi_2$ such that both have at most k variables in common and both depend on at least $n - \frac{k}{2}$ variables which do not occur in the other formula.*

Proof. We briefly sketch how the splitting of ϕ done in Lemma 1 can be performed more carefully such that both formulas ϕ_1 and ϕ_2 depend at least on a certain number of variables. For notational simplicity assume k to be even. Let $(X_1, X_2, \ldots, X_p)$ be a path-decomposition of $P(\phi)$; order the variables once again as done in the proof of Lemma 3. Denote the ordered sequence by $v_1 < \ldots < v_{2n}$. Choose $i := n + \frac{k}{2}$ and let $X_\ell := \underline{X}(v_i)$. Define ϕ_1 as conjunction of those clauses in ϕ containing only variables among the $v_1, \ldots, v_i$ and ϕ_2 as conjunction of all remaining clauses. Remark, that the $n - k/2$ variables $v_{i+1}, \ldots, v_{2n}$ do not occur in ϕ_1. Due to the path-width conditions the common variables in ϕ_1 and ϕ_2 must be variables in X_ℓ. Thus, there are at most k many. Moreover, X_ℓ contains at most k among the $n + \frac{k}{2}$ many variables $x_1, \ldots, x_i$. Therefore at least $n - \frac{k}{2}$ of these occur for the last time in some $X_{\ell'}$, where $\ell' < \ell$ and ϕ_2 cannot depend on them. □

As consequence, Lemma 1 now also holds with respect to the best-case communication complexity (Definition 8) of the function represented by ϕ.

Corollary 1. *The best-case communication complexity of a function $f : \{0,1\}^{2n} \to \{0,1\}$ is lower than $k+1$, where $k-1$ is the path-width of the primal graph of any CNF formula computing f.*

Proof. Let ϕ be a formula computing f, and $k-1$ be its path-width. By Lemma 4, one can write ϕ as a conjunction $\phi_1 \wedge \phi_2$, where ϕ_1 and ϕ_2 have each $n - k/2$ variables not shared with the other formula. Let us consider a variable partition (x, y), where x contains the $n-k/2$ variables, that belong to ϕ_1 exclusively, and y the $n - k/2$ variables, that belong to ϕ_2 exclusively, the remaining variables being distributed arbitrarily so that $|x| = |y| = n$.

With this variable partition, the communication complexity of $f(x, y)$ is lower than $k + 1$. Indeed, two processors, one having the variables x and the other one the variables y, can exchange the at most $k/2$ variables that the first need to compute ϕ_1, and the at most $k/2$ variables that the second need to compute ϕ_2. Then, if the first processor sends the result of its computation on ϕ_1 - which is a single bit - the second can return the value of f.

Thus, the best case communication complexity is lower than $k + 1$.

If for a function f the best-case communication complexity is known, then we can use the corollary to deduce lower bounds for the path- and tree-width of CNF formulas representing f.

Example 1. For $x, y \in \{0,1\}^n, 1 \leq i \leq n$ consider the boolean function $SEQ(x, y, i)$ which gives result 1 iff the string $x = x_0 x_1 \ldots x_n$ equals the string y shifted circularly by i bits to the right, that is to $y_i y_{i+1} \ldots y_{n-1} y_0 \ldots y_{i-1}$. It is known [11] that SEQ has a best case communication complexity which is at least linear in the size of the input. Thus, the path-width of the primal graph of any CNF formula computing SEQ is at least linear in the input.

The same argument holds as well for the function $PROD(a, b, i)$ which computes the i-th bit of the product $a \cdot b$, for the function $MATCH$ which on a $3m$-string x and a m-string y returns 1 iff y is a substring of x, and for the function $USTCON$ which on a graph with ℓ vertices and two given vertices s and t outputs 1 if there exists a path from s to t. As noted in [11] the best-case communication complexity of those function is, respectively, linear, $\Omega(m/\log(m))$ and $\Omega(\sqrt{n})$. Consequently, they do not admit CNF formulas of path-width, respectively, linear, $\Omega(m/\log(m))$ and $\Omega(\sqrt{n})$.

Since the path-width p and the tree-width t are related via $p = O(t \cdot \log n)$, all above mentioned examples do not admit CNF formulas with a primal graph of bounded or even logarithmic tree-width.

4.2 Hardness for clique-width

The question answered negatively by Theorem 7 for tree-width can be posed as well in relation to the clique-width parameter. That is: Can the permanent function be described via CNF formulas of bounded clique-width and polynomial size? Next we relate this question to Theorem 2 b) and show that such a representation is only possible if the conjecture $\#P \not\subseteq FP/poly$ fails to be true.

Theorem 8. *Suppose there is a family $\{\varphi_n\}_n$ of CNF formulas of polynomial size such that all $I(\varphi_n)$ are of clique-width at most k for some fixed k and for each $Y \in \{0,1\}^{n^2}$ we have that $\varphi_n(Y)$ holds iff Y is a permutation matrix. Then $\#P \subseteq FP/poly$.*

Proof. Suppose $\{\varphi_n\}$ is given as in the assumption. For a matrix $X \in \{0,1\}^{n^2}$ we shall construct from φ_n and a parse-tree of it (given as non-uniform advice) another CNF formula $\psi_n^X(Y)$ of bounded clique-width together with a parse-tree for ψ_n^X such that

$$Perm(X) = \sum_{Y \in \{0,1\}^{n^2}} \psi_n^X(Y).$$

Theorem 2 b) implies that the latter can be computed in polynomial time. Given $\#P$-completeness of the permanent function on 0-1-matrices the claim follows.

The construction of ψ_n^X works as follows. It is $Perm(X) = \sum_{Y \in \{0,1\}^{n^2}} \varphi_n(Y) \cdot X^Y$, where $X^Y = \prod_{i,j} x_{i,j}^{y_{i,j}}$ and $x_{i,j}^{y_{i,j}} = \begin{cases} x_{i,j} \text{ if } y_{i,j} = 1 \\ 1 \quad \text{else} \end{cases}$. We replace the monomial X^Y by the conjunctions $\bigwedge_{i,j}(x_{i,j} \vee \neg y_{i,j})$. The clause graph $I(\psi_n)$ of the CNF formula

$$\psi_n(X,Y) \equiv \varphi_n(Y) \wedge \bigwedge_{i,j}(x_{i,j} \vee \neg y_{i,j})$$

can easily be seen to have clique-width $\leq k+2$. Each time when in the clique-width construction of $I(\varphi_n)$ along the parse-tree a node $y_{i,j}$ is created, in the corresponding construction for $I(\psi_n)$ two new nodes for $x_{i,j}$ and the clause $D_{i,j} := x_{i,j} \vee \neg y_{i,j}$ are created with an own label each. Then $D_{i,j}$ is connected to both $x_{i,j}$ and $y_{i,j}$ (respecting the necessary signs of the edges). Finally the labels for $D_{i,j}$ and $x_{i,j}$ are removed again.

Now for a fixed given matrix X we plug the values of the $x_{i,j}$ into the CNF formula $\psi_n(X,Y)$. Clauses that are satisfied by the assignment are removed. In clauses that are not satisfied by the assignment all occurences of $x_{i,j}$ literals are removed. That way a new CNF formula ψ_n^X is obtained. The clause graph $I(\psi_n^X)$ results from $I(\psi_n)$ by

(i) removing certain nodes (the $x_{i,j}$ as well as some clause nodes) and
(ii) identifying certain clause nodes.

Both operations do not increase the clique-width. Being clear for (i) it is also true for (ii) since two or several clauses that are identified after having assigned values to the $x_{i,j}$'s must contain the same $y_{i,j}$'s. Thus, this part has been dealt with in the parse-tree construction for $I(\psi_n)$ already and can be taken as well for the parse-tree construction of $I(\psi_n^X)$. □

The result holds as well if we allow additional variables in $\varphi_n(Y)$ as in the statement of Theorem 7. It remains an open question whether Theorem 8 can be strengthened to hold unconditionally, like Theorem 7:

Conjecture: There is no family $\{\varphi_n\}_n$ of CNF formulas of polynomial size with all $I(\varphi_n)$ of bounded clique-width such that $\varphi_n(Y) \Leftrightarrow Y$ is a permutation matrix.
